ABSTRACT

This work is concerned with elastic and inelastic scattering of ions and atoms.

Semi-classical and quantal phase shift treatments are applied to the system of lithium ions in helium. A SCF-MO calculation of the interaction potential for the ground state of the system is reported and the results compared with other quantal calculations and with semi-empirical cross-sections. The cross-section for scattering through an angle greater than a given angle, the total elastic cross-section, the diffusion cross-section and the mobility are obtained and compared with experiment. The presence of orbiting is seen in the total cross-sections. It is predicted that the SCF-MO potential supports seven bound vibrational states.

A classical binary encounter impulse approximation is applied to ionization of atoms. The velocity distribution of the bound atomic electrons is given by Hartree Fock wave function. Inner and outer shell ionizations cross-sections of atomic helium, lithium, oxygen, nitrogen and neon by electron and proton impact are calculated. The results are compared with other classical and quantal calculations, and where possible with experiment.

Finally the excitation of atomic hydrogen by proton impact is considered within the framework of the impact parameter model. The closure approximation, which implicitly takes account of all rearrangement channels, is used to obtain excitation cross-sections into the 2s-state. The calculation is performed retaining only two states explicitly and the results are compared with those predicted by other quantal treatments. No experimental results are available for comparison.

ACKNOWLEDGEMENTS

I should like to express my gratitude to Professor M.R.C. McDowell for his continuous encouragement and guidance throughout this work.

Also my thanks are due to Dr. I.M. Cheshire for some most informative discussions relating to the final chapter herein. I am indebted to Dr. G. Peach and Professors J.C. Browne and F.T. Smith for use of results prior to publication.

Finally, I am indebted to the Science Research Council for a maintenance grant for the duration of the work.

CHAPTER I

MODELS OF HEAVY PARTICLE COLLISIONS

1. Introduction

The theory of ion-atom collisions can be considerably simplified by adopting models and using approximations that take advantage of the comparatively large masses involved in the collision. The present work investigates both elastic and inelastic collisions for some ion-atom systems using classical, semi-classical and quantal treatments.

In general, for elastic collisions, the nuclei can be considered as moving in some averaged field due to the interaction of all particles (nuclei & electrons) in the system in a way in which, in the absence of excitations, allows their motion to be considered independently of the electrons. Such a separation of nuclear and electron motion was first demonstrated by Born and Oppenheimer (1932). The collision can then be represented by a potential scattering model.

A classical potential scattering analysis is applicable if the de Broglie wave length associated with the collision is small compared with atomic dimensions, which is the case for heavy particle collisions above thermal energies. However it is well known that the classical analysis fails

for total elastic cross-sections for the realistic infinite potentials that will be considered in this present work, but it may be valid for differential elastic cross-sections, $I(\theta)$, over a wide range of angles say $\theta > \theta_c > 0$. An estimate of this critical angle θ_c below which the classical analysis fails can be obtained from the uncertainty principle, and for protons above thermal energies is of the order of 0.1° (Mott and Massey 1965). At thermal energies, semi-classical (see section 2) and quantal treatments are required.

Classical models of inelastic scattering would be expected to be adequate if the dominant contribution to the cross-sections came from angles greater than θ_c . For example if energy transfers greater than ΔE are required for ionization, there is a corresponding angle $\theta_0(E)$ such that for $\theta < \theta_0$ the energy transferred is insufficient to cause the transition. Then for energies such that $\theta_0(E) > \theta_c$, it can be expected that classical models could adequately describe ionization. The major argument against the application of a classical theory is that the theory is unable to describe distant collisions correctly. This is reflected in the high energy region of the cross-sections where the distant collisions make a significant contribution. For example the behaviour of the classical ionization cross-section at high energies is E^{-1} in disagreement with the correct quantal result of $E^{-1} \ln E$.

Ion-atom collisions with energies in the kilovolt

region, can be described in the impact parameter model. In this model the nuclei are treated as classical particles describing rectilinear trajectories with constant velocity and the electrons are treated quantum mechanically as they move in the time dependant fields of the "infinitely massive" nuclei. Mittleman (1961) has shown these assumptions not to be unjustified in this energy region.

The following sections of this chapter will be devoted to elastic ion-atom scattering, classical theory of inelastic collisions and impact parameter treatments of heavy particles respectively. In view of the range of topics included, a comprehensive review of the theory and previous work in these fields will not be attempted (see Coleman & McDowell, 1969) but the discussion will be such as to introduce the particular theoretical models that will appear in Chapters II, III, IV.

2. Elastic Ion-Atom Collisions

In the absence of inelasticity, the Born-Oppenheimer separation allows ion-atom collisions to be treated in a central potential model. The exact quantum treatment for spherically symmetric potentials using the Faxen-Holtzmark method of partial waves is well known (Mott & Massey 1965) and the results will only be stated here. The differential cross-section $I(\theta)$ is given in terms of an elastic scattering amplitude, $f(\theta)$

$$f(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} (2\ell+1) \left[2e^{2i\eta_{\ell}-1} \right] P_{\ell}(\cos\theta) \quad (1.1)$$

such that

$$I(\theta) = |f(\theta)|^2. \quad (1.2)$$

Here $P_{\ell}(x)$ is the Legendre polynomial of order ℓ and η_{ℓ} is the ℓ -order phase shift defined by the requirement that the asymptotic form of the regular solution of the radial equation.

$$\left[\frac{d^2}{dr^2} + k^2 - 2\mu V(r) - \frac{\ell(\ell+1)}{r^2} \right] u_{\ell}(r) = 0 \quad (1.3)$$

should be

$$u_{\ell}(r) \underset{r \rightarrow \infty}{\sim} \sin(kr - \frac{1}{2}\ell\pi + \eta_{\ell}) \quad (1.4)$$

where in the usual notation, k is the momentum of the collision, μ is the reduced mass, $V(r)$ is the interaction potential and ℓ is the angular momentum quantum number. Hence the phase shift η_{ℓ} refers to the displacement of the solution of the radial equation at large distances relative to that of the corresponding ℓ th order spherical Bessel function, $j_{\ell}(kr)$. (krj_{ℓ} is a solution of (1.3) for $V(r) = 0$). Thus, given any realistic potential function, one solves (by numerical methods) the equation for successive values of ℓ evaluating a sufficient number of phase shifts to obtain convergence (to some specified limit of accuracy) in the sum over ℓ in eqn. (1.1).

However a complete quantal phase shift analysis can be prohibitively time consuming when large numbers of phase shifts are required. Ford and Wheeler (1959), and more recently

Munn, Mason and Smith (1964) and Bernstein (1966), have examined the effect of "semi-classical" approximations in the derivation of the phase shifts on the behaviour of the phase shifts and on the scattering observables.

The two main deviations from the quantal analysis which are made to obtain the semi-classical approximation are:

(i) The exact phase shifts are replaced by JWKB phase shifts (see Coleman and McDowell 1969). The approximate solution of Jeffreys to eqn. (1.3) from which the JWKB phases are determined, is valid when the potential does not vary appreciably in a distance comparable with the wave length $1/k$ of the collision. The JWKB phase shift can be written as

$$\eta_{\ell}^{\text{JWKB}} = \lim_{r \rightarrow \infty} \left[\int_{r_m}^r (k^2 - 2\mu V(r) - (\ell + 1/2)^2/r^2)^{1/2} dr - \int_{(\ell + 1/2)/k}^r (k^2 - (\ell + 1/2)^2/r^2)^{1/2} dr \right] \quad (1.5)$$

where r_m is the classical turning point.

When ℓ is sufficiently large (eg. $\ell \sim kR$ where R is some "range" parameter of the potential), Massey and Mohr (1934) showed that (1.5) could be simplified by expanding the first integrand to yield the so called Jeffreys-Born phase shift.

$$\eta_{\ell}^{\text{JB}} = - \int_{\frac{\ell + 1/2}{k}}^{\infty} \frac{\mu V(r) dr}{(k^2 - (\ell + 1/2)^2/r^2)^{1/2}} \quad (1.6)$$

(ii) The summations of the phase shifts to produce cross-sections are approximated by integrals.

The validity of the first approximation has been examined by Munn et al (1964) for a L-J (12,6) potential. The approximation is essentially valid for "large" k and they show there is always a region of l and k for which the approximation is poor, and this region is dependant on the potential parameters and the reduced mass of the collision. The success or prior calculations using JWKB phase shifts and semiclassical analysis (Bernstein (1960), Marchi and Mueller (1962, 1963)) was due to avoidance, for the most part, of these regions.

Massey and Mohr (1934) obtained an approximate expression (in closed form) for the total elastic cross-section by considering two regions of angular momentum. The first where the phase shifts are large and essentially random and the random phase approximation is applicable, and the second where they are small and non-random but for which the cross-section summation (Chapter II, eqn. (2.6)) can be replaced by an integral over the JB eqn. (1.6), approximation to the phase shift. These approximations produce the Massey-Mohr cross-section. Landau and Lifshitz (1959) obtained a more accurate formula by replacing the whole sum by an integral over the JB phase shifts. (Schiff (1956) obtained an identical expression using an independent treatment and the cross-section in the analysis will be called the SLL approximation).

Undulatory deviations from the Massey-Mohr cross-

section caused by regions of stationary phase corresponding to glory scattering, were predicted by Bernstein (1961) and have since been observed experimentally (Rothe et al, 1962).

Bernstein (1962, 1963) then semi-classically related the number of oscillations to the number of bound states (vibrational-rotational) that the potential can support. Because the semi-classical analysis fails for thermal energies the relationship is not rigorous and can only be stated as "The observation of m maxima in the elastic cross-section implies the existence of at least m vibrational bound states." (Bernstein, 1966)

Rainbow scattering also causes structure in the cross-section and if an estimate of the number of vibrational bound states is to be deduced from the behaviour of the total cross-section using the Bernstein relationship, then this structure must be identified and subtracted out before hand. (Munn et al, 1964)

It is known that a semi-classical analysis including approximations (i) and (ii), reduces transport cross-sections to the results obtained by exact classical methods, which are in error for low energies where orbiting and resonance effects occur. It is thus necessary to revert to the exact quantal analysis for such results (Dickenson 1968a, b).

When averaging over transport cross-sections to obtain mobilities much of the structure in the quantal cross-section is lost and semi-classical analysis predicts mobilities which are in reasonable accord with experiment for a

wide temperature range (Dalgarno et al (1958), Dalgarno (1958)).

Experimental results of differentially scattering can be used to predict interaction potentials using inversion techniques (Hoyt (1939), Firsov (1953)). However the resultant potentials are only available for a restricted range of internuclear separation and completely unsuitable for collisions in the thermal energy range. Recently with the development of fast digital computers, accurate a priori quantal calculations of the potentials have become possible and are comprehensively reviewed by Krauss (1967).

3. Classical Models of Inelastic Scattering

The classical binary encounter impulse approximation has been used to describe ionization, excitation and charge-transfer in electron-atom and ion-atom collisions but the following discussion will be in the main concerned with ionization. The basic assumptions of the theory are:

- (i) The projectile describes a classical orbit.
- (ii) The mutual interaction between the atomic electron and nucleus are disregarded during the collision. This is known as the impulse approximation.
- (iii) The interaction of the target electrons with the projectile are treated independently. This is the binary encounter approximation.
- (iv) The projectile is regarded as a structureless particle.
- (v) The interactions of the projectile with the target particles are Coulombic.

The cross-section for any process will be obtained from the formulae

$$Q = N \int d(\Delta E) \frac{d\sigma}{d(\Delta E)} \quad (1.7)$$

where $d\sigma/d(\Delta E)$ is the differential cross-section for a given energy transfer, N is the effective number of electrons in the target and the integral is taken over those values of the energy transfer which contribute to the process under consideration. In the case of excitation and charge transfer a difficulty arises. Only one value of ΔE is relevant, namely the value which corresponds to the difference between the initial and final binding energies (given by quantal treatments of the electronic states or the use of empirical evidence), and the integral (1.7) vanishes. It is necessary to assume that a specific excitation or charge-transfer process will occur if the energy transfer, ΔE , satisfies

$$E_1 < \Delta E < E_2$$

for suitable E_1 and E_2 . Similarly we assume ionization will occur if the energy transfer exceeds the binding energy of the atomic electron.

The atomic electrons in this model are assumed to be independent scattering centres. This assumption is justified when the effective interaction between the projectile and target takes place in a region small compared with atomic dimensions. If this is the case, the energy transfer to the target electron is far greater than the binding energy, and the model should therefore be more accurate when applied to ionization processes than for excitation and charge transfer.

Also for ionization there is no ambiguity in choosing the classical band of energies to represent the final state whereas for excitation and charge-transfer this is not the case.

In the following analysis let m_1 and m_2 be the masses of a target electron and incident projectile with charge z . (designated by 1 and 2 respectively) and let \underline{v}_1 and \underline{v}_2 be their initial velocities in the laboratory frame. Then the energy transfer cross-section is

$$\frac{d\sigma(\underline{v}_1, \underline{v}_2)}{d(\Delta E)} = \frac{2\pi V_g^2 z^2}{V^2 |\Delta E|^3} \left(1 - \cos^2 \psi + \frac{\Delta E}{\mu V V_g} \cos \psi \right) \quad (1.8)$$

where ΔE is the energy transfer, μ is the reduced mass, \underline{V}_g is the constant velocity of the centre of mass, \underline{V} is the initial relative velocity and ψ is the angle between \underline{V}_g and \underline{V} . (For a detailed derivation of this, and following equations, see Coleman & McDowell 1969). The range of ΔE is restricted by the inequality.

$$-1 \leq \cos \psi - \frac{\Delta E}{\mu V V_g} \leq 1 \quad (1.9)$$

and this ensures that $d\sigma/d(\Delta E)$ is a positive quantity.

Thomson (1912) considered the simple case where the atomic electron is at rest (ie. $\underline{v}_1=0$). The ionization cross-section at impact energy E_2 is given by

$$Q_T(E_2) = \int_I^E \frac{d\sigma(0, \underline{v}_2)}{d(\Delta E)} d(\Delta E) \quad (1.10)$$

where I is the binding energy of the atomic electron and E is

the maximum value of ΔE such that the inequality (1.9) is satisfied. It is convenient to use atomic units, then $m_1 = 1$ and

$$Q_T(E_2) = \frac{z^2 m_2}{E_2 I} \left[1 - \frac{I}{E_2} \frac{(m_2 + 1)^2}{4m_2} \right] (\pi a_0^2). \quad (1.11)$$

In the high energy limit the Thomson ionization cross-section is proportional to E_2^{-1} which is in disagreement with both quantal treatments and experiment which both behave as $E_2^{-1} \ln E_2$.

In order to investigate the cross-section near threshold, let

$$E_2 = I + \epsilon \quad \epsilon \ll I$$

and a linear dependence on the excess energy near threshold immediately follows for electron impact ($m_2=1$). This is in agreement with the quantal result of Rudge and Seaton (1965) for electron impact ionization of atomic hydrogen. For heavy particle impact the model fails completely near threshold because of the unrealistic assumption to consider the atomic electron fixed ($v_1=0$) in comparison with the heavy particle at these energies. For example in the case of proton impact ionization of hydrogen, the Thomson cross-section vanishes below 6.25 k.e.V.

The derivation of eqn. (1.8) is completely symmetric with respect to the two particles. When we consider the scattering of a beam of particles with initial velocity v_2 , the relevant differential cross-section is related to that in (1.8) by a invariant reaction rate and is given by

$$\frac{d\sigma_2(\underline{v}_1, \underline{v}_2)}{d(\Delta E)} = \frac{v}{v_2} \frac{d\sigma(\underline{v}_1, \underline{v}_2)}{d(\Delta E)} \quad (1.12)$$

For $v_1 = 0$, the cross-sections become identical.

For an isotropic distribution of \underline{v}_1 , eqn.(1.12) may be averaged over angles,

$$\frac{d\sigma_2(v_1, v_2)}{d(\Delta E)} = \frac{1}{4\pi v_2} \int_C v \frac{d\sigma(\underline{v}_1, \underline{v}_2)}{d(\Delta E)} d\Omega \quad (1.13)$$

where C denotes the solid angle (for given E_1 , E_2 , and E) in which the inequality (1.9) is satisfied. The ionization cross-section is then given by

$$Q(E_1, E_2) = \int_I^{E_2} \frac{d\sigma_2(v_1, v_2)}{d(\Delta E)} d(\Delta E) \quad (1.14)$$

Stabler (1964) performed both these integrations for electron impact ionization (ie. $m_1=m_2=1$) and obtained cross-sections in closed form.

$$\begin{aligned} Q(E_1, E_2) &= \frac{2}{3E_2 I^2} \frac{(E_2 - I)^{3/2}}{E_1^{1/2}} (\pi a_0^2) \quad E_2 \geq E_1 + I \\ &= \frac{1}{3E_2} \left[\frac{2E_1 + 3I}{I^2} - \frac{3}{E_2 - E_1} \right] (\pi a_0^2) E_2 \leq E_1 + I \end{aligned} \quad (1.15)$$

As early as 1927, Thomas (1927a, b) and Williams (1927) had independently refined the theory of Thomson by considering the atomic electrons to have a spherically

symmetric velocity distribution. They derived expressions for $d\sigma_2(v_1v_2)/d(\Delta E)$ by performing the integration in (1.13) but only obtained results for restricted energy ranges and hence were unable to derive the ionization cross-sections (1.15). More recently Gryzinski (1959) derived classical relations for coulombic collisions of two moving particles and laid the foundations for Stabler(1964) to derive the ionization cross-sections for the "equal mass" case obtaining agreement with the Thomas-Williams energy transfer cross-section in the process.

McDowell (1966) and Vriens (1967) have pursued the theory for unequal masses. McDowell, for proton impact ionization of hydrogen evaluated eqn. (1.13) in closed form and then numerically integrated (1.14) to obtain the ionization cross-section. Vriens introduced the momentum transfer as a variable in the analysis and obtained ion-impact ionization cross-sections to first order in $1/m_2$ in closed form in a simple way.

$$\begin{aligned}
 Q(E_1, E_2) &= \frac{2z^2}{v_2^2} \left[\frac{1 + \frac{v_1^2}{3I^2}}{I} - \frac{1}{2(v_2^2 - v_1^2)} \right] (\pi a_0^2) I \leq 2v_2(v_2 - v_1) \\
 &= \frac{z^2}{v_2^2} \left[\frac{1}{2v_1(v_2 + v_1)} + \frac{1}{I} + \frac{1}{3v_1} I^2 \left(2v_2^3 + v_1^3 - (2I + v_1^2)^{3/2} \right) \right] \\
 &\quad (\pi a_0^2) \quad 2v_2(v_2 - v_1) \leq I \leq 2v_2(v_2 + v_1) \quad (1.16) \\
 &= 0, \text{ otherwise.}
 \end{aligned}$$

Gerjuoy (1966) derived energy transfer cross-sections for unequal masses, and in the relevant energy regions they were identical to the much earlier formulae of Williams (1927). Garcia, Gerjuoy and Welker (1968) using these cross-sections performed the integration (1.14) analytically and obtained exact classical ionization cross-sections for ion-impact with bound electrons at fixed non zero velocity.

The cross-section (1.14) is given for fixed values of E_1 & E_2 and it should therefore be averaged over the velocity distribution, $f(v_1)$, of the bound electrons to give an ionization cross-section

$$Q(E_2) = \int_0^{\infty} Q(E_1 = \frac{1}{2}v_1^2, E_2) f(v_1) dv_1 \quad (1.17)$$

where, of course,

$$\int_0^{\infty} f(v_1) dv_1 = 1. \quad (1.18)$$

McDowell (1966) calculated $Q(E_2)$ for electron and proton impact ionization of hydrogen using the classical micro-canonical velocity distribution for the atomic electrons (Mapleton 1966) which is identical to the quantal result. Because of the lack of knowledge of velocity distributions in other systems, it is usual to assume

$$f(v_1) = \delta(v_1 - (2I)^{1/2}) \quad (1.19)$$

Prasad and Prasad (1963) with this assumption used the early Gryzinski theory to calculate ionization cross-sections for several atoms and diatomic molecules. Bauer and Bartky (1965) further extended the theory to excitation and ionization of molecules. Proton impact ionization cross-sections for noble gases have been performed by Garcia et al (1968).

In general the results are in excellent agreement, considering the simplicity of the model, with quantal calculations and experiment, differing at most by a factor of two up to large impact energies. The failure of the classical model to take account of distant collisions causes the high energy limit of the ionization cross-section to behave as E^{-2} in disagreement with both the experimental and quantal result of $E^{-1} \ln E$.

The above models with minor refinements have been applied by numerous workers to other processes such as excitation (Kingston 1964a,b, 1966a,b) and charge transfer (Thomas 1927, Bates & Mapleton 1967, amongst others) without the same measure of success in reproducing experimental and quantal results.

Finally, Percival and his collaborators (Abrines & Percival 1964, 1966a, b) have considered classical models of proton impact ionization of atomic hydrogen in which the target gas is represented by a classical microcanonical ensemble of two body (e+p) systems which are allowed to interact classically with the incident proton. The Newtonian equations

of motion of the three particles are then solved numerically for a wide range of impact parameters, incident energies and a suitable distribution of two body systems. The resultant trajectories are examined to see whether as $t \rightarrow \infty$, they represent a bound orbit of the initial target pair, electron transfer to the incident proton or three free particles (ionization).

4. Impact Parameter Methods

For not too low impact velocities, the theory of collisions between atomic systems can be considerably simplified by considering it within the frame-work of the impact parameter model. In this model the motion of the heavy nuclei are not only treated classically, but in most cases the motion is assumed to be rectilinear and can be uniquely distinguished by an impact parameter $\underline{\rho}$ and a velocity \underline{v} . The electrons are treated quantum mechanically in the time dependant field of the nuclei.

The following discussion will be confined to proton-hydrogen collisions as this avoids unnecessary algebraic complexity in the analysis without undue loss in generality.

Electron transitions of the type

(direct excitation) and

(rearrangement) will be considered.

In the impact parameter model, the target nucleus, A, is assumed to be at rest and the proton, B, moves in a straight line with velocity \underline{v} . Let \underline{R} be the position vector of B relative to A then

$$\underline{R} = \underline{\rho} + \underline{v}t$$

where the time, t , is chosen so that A and B have a minimum separation ρ at $t=0$. Denote the centre of mass by 0 then let the position vectors of the electron, e , relative to A, B and 0 be \underline{x} , \underline{s} and \underline{r} respectively.

The time dependant Schrodinger equation (in atomic units) for the complete electronic wave function $\Psi(r,t)$ is

$$(T_A + V_B)\Psi = 0 \quad (1.22)$$

where

$$T_A = \frac{1}{2}\nabla_r^2 + \frac{1}{x} + i\frac{\partial}{\partial t} \quad V_B = \frac{1}{s} \quad (1.23)$$

Let $\phi_i(r)$ denote the hydrogenic eigenfunction with eigen-energy ϵ_n which satisfies

$$\left(\frac{1}{2}\nabla^2 + \frac{1}{r} + \epsilon_n\right) \phi_n(r) = 0 \quad (1.24)$$

To allow for the translation motion of the protons, Bates and McCarroll (1958) introduced travelling orbitals

$$\phi_n^A(\underline{x}) = \phi_n(x) \exp \left[-i \left(\frac{1}{2}\underline{v} \cdot \underline{r} + \frac{1}{8}v^2 t + \epsilon_n t \right) \right] \quad (1.25)$$

and it is readily shown that

$$T_A \phi_n^A = 0 \quad (1.26)$$

The boundary conditions (as $t \rightarrow -\infty$) of the required solution of (1.22) must describe an electron bound to the proton A in a state p, say. In early impact parameter treatments (c.f. Bates 1958), it was assumed that a sufficient boundary condition was given by ignoring the term V_B in (1.20) for large t, and hence the boundary condition was

$$\Psi \underset{t \rightarrow \infty}{\sim} \phi_p^A(x).$$

Cheshire (1964) showed that the Coulomb potential V_B has a residual effect at large t and the boundary condition should be multiplied by a phase factor and is given by

$$\Psi \underset{t \rightarrow -\infty}{\sim} \phi_p^A(\underline{x}) \exp\left[-\frac{i}{v} \ln(vR - v^2 t)\right] \quad (1.27)$$

For excitation transitions it is convenient to consider a formal expansion of

$$\Psi = \Phi^A A \quad (1.28)$$

where Φ^A is a row matrix with elements ϕ_n^A and A is a column matrix with elements $a_n(t)$ with boundary conditions.

$$a_n(t) \underset{t \rightarrow -\infty}{\sim} \delta_{np} \exp\left[-\frac{i}{v} \ln(vR - v^2 t)\right] \quad (1.29)$$

The scalar product in (1.28) implies summation over all bound states and integration over the continuum. The probability of excitation to a bound state q, also on A, is given by

$$P_A(p, q) = \lim_{t \rightarrow \infty} \left| a_q(t) \right|^2 \quad (1.30)$$

The Schrodinger equation may also be written

$$(T_B + V_A) \Psi = 0 \quad (1.31)$$

where

$$T_B = \frac{1}{2} \nabla_r^2 + \frac{1}{s} + i \frac{\partial}{\partial t} \quad V_A = \frac{1}{x} \quad (1.32)$$

and travelling orbitals centred on the proton B are given by

$$\phi_m^B = \phi_m(s) \exp \left[i \left(\underline{v} \cdot \underline{r} - \frac{v^2 t}{8} - \epsilon_n t \right) \right] \quad (1.33)$$

When considering rearrangement collisions, it is convenient to expand Ψ , in parallel with (1.28), as

$$\Psi = \phi^B_B \quad (1.34)$$

and the probability that the electron is finally bound to proton B in state q is given by

$$P_B(p, q) = \lim_{t \rightarrow \infty} \left| b_q(t) \right|^2. \quad (1.35)$$

The major difficulty of such an expansion (1.34), is that the boundary condition of the solution Ψ as $t \rightarrow -\infty$ describing a bound state of A, cannot be represented by a linear combination of functions ϕ^B centred on proton B. It is thus necessary to also include an expansion of the form (1.28) in the analysis of charge transfer collisions.

Finally, cross-sections for transitions (1.20) and (1.21) are obtained by integrating the relevant probabilities over all impact parameters.

$$Q_{A,B}(p, q) = \int d\rho \, P_{A,B}(p, q). \quad (1.36)$$

It has long been realized (Frame (1931)) that the cross-sections given by (1.36) are equivalent to the exact (non-relativistic) quantum theory result provided that the impact energy is much larger than the energy transfer involved in the collision. Following Moiseiwitch (1966) and Crothers and Holt (1966), McCarroll and Salin (1966) proved this result with the added restrictions equivalent to ensuring that the deBroglie wavelength of the relative motion is small compared with atomic dimensions so that the orbit of the heavy particle may be described in an unambiguous way.

More recently, McCarroll and Salin (1968) have considered the impact parameter formulation in terms of a purely quantal formalism in the limit as the masses of the atomic nuclei become infinite and have succeeded in obtaining expressions for differential scattering cross-sections in terms of amplitudes obtained from the impact parameter calculation.

A few previous applications of the impact parameter model will now be considered. Projecting the Schrodinger equation (1.22), on the complete set of states ϕ^A results in a equivalent set of equations

$$(\phi^A | T_A | \psi) = -(\phi^A | V_B | \psi) \quad (1.38a)$$

Similarly for equation (1.31) and ϕ^B ,

$$(\phi^B | T_B | \psi) = -(\phi^B | V_A | \psi) \quad (1.38b)$$

where

$$(\phi_n^{A,B} | Z | \psi) = \int d\underline{r} \phi_n^{A,B*} Z \psi \quad (1.39)$$

Using the expansion (1.28) of Ψ and equation (1.26), (1.38a) reduces to

$$\frac{dA}{dt} = i(\phi^A | V_B | \phi^A) A \quad (1.40)$$

This is an infinite set of coupled differential equations for the variables $a_n(t)$ and is exact up to this point within the framework of the impact parameter model. In practice these equations are reduced by neglecting all terms containing states other than the few bound states considered to be most dominant in the collision (e.g. initial, final and an intermediate state). One would hope that as more intermediate states are included the final transition amplitude would converge to the correct results.

If only the diagonal elements in (1.40) are retained then

$$a_n = \delta_{np} \exp \left[i \int^t \left(\phi_n^A | V_B | \phi_n^A \right) dt' \right] \quad (1.41)$$

The distortion approximation of Bates (1959) for excitation into state q , is obtained from (1.40) by retaining only terms containing states p and q

$$\dot{a}_q = i \left(\phi_q^A | V_B | \phi_q^A \right) a_q + i \left(\phi_q^A | V_B | \phi_p^A \right) a_p \quad (1.42)$$

and substituting from (1.41) for a_p . This procedure can be extended by retaining more states and solving the coupled equations numerically (Lovell & McElroy, 1965) but the usefulness of (1.40) is extremely limited as it contains no coupling to

the important rearrangement states on proton B, and so the hope of converging on the correct solution by the addition of more states, can never be realized.

As an alternative to (1.40), we can consider the equations

$$\frac{dA}{dt} = i(\phi^A | V_B | \phi^B) B \quad (1.43a)$$

$$\frac{dB}{dt} = i(\phi^B | V_A | \phi^A) A \quad (1.43b)$$

obtained from (1.38a, b) using expansions (1.35) and (1.28) respectively. Rearrangement amplitudes can be obtained using (1.43b) once the matrix A is known. The Brinkman-Kramers approximation is obtained by substituting $a_n = \delta_{np}$, but as Cheshire (1965) pointed out, this is inconsistent with the boundary conditions (1.29). The modified Brinkman-Kramers approximation is obtained using

$$a_n = \delta_{np} \exp \left[-\frac{i}{v} \ln(vR - v^2 t) \right] \quad (1.44)$$

in the right hand side of (1.43b).

It is easily shown that the only effect of the addition of an arbitrary function, $W(R)$, of the internuclear distance to the Hamiltonian of the Schrodinger equation (1.31), is to change the exact solution Ψ by a phase factor and hence will leave the calculated cross-sections unchanged. Bates and Dalgano (1952), and Jackson and Schiff (1953) performed rearrangement calculations including the nuclear-nuclear interaction term in the matrix elements and hence

solved

$$(T_B + V_A^1) \Psi = 0 \quad (1.45)$$

where

$$V_A^1 = \frac{1}{x} + \frac{1}{R} \quad (1.46)$$

and with the boundary condition given by

$$\Psi \underset{x \rightarrow -\infty}{\sim} \Phi_p^A(x) \quad (1.47)$$

The exact solution Ψ , is identical to that obtained from (1.31) (1.32) and (1.27). This is not true when Ψ is represented by truncated expansions of atomic orbitals and the cross-sections of Bates & Dalgarno differed from the Brinkman-Kramers approximation. We now have the unsatisfactory situation where the cross-sections are not independent of the nuclear-nuclear interaction potential.

To rectify this, Bates (1958) proposed an over complete expansion

$$\Psi = \Phi_A^A + \Phi_B^B$$

The advantage of this two centre expansion is that it makes explicit allowance for each reaction path and circumvents the defect of the single centre expansion where rearrangement states are contained in the continuum. Substituting (1.49) in (1.38a, b) gives

$$\frac{dA}{dt} + (\Phi^A | \Phi^B) \frac{dB}{dt} = i(\Phi^A | V_B | \Phi^A)A + i(\Phi^A | V_A | \Phi^B)B \quad (1.50)$$

$$\frac{dB}{dt} + (\Phi^B | \Phi^A) \frac{dA}{dt} = i(\Phi^B | V_A | \Phi^B)B + i(\Phi^B | V_B | \Phi^A)A \quad (1.51)$$

and these equations, when truncated, give cross-sections that are unaffected by the addition of $W(R)$ to the Hamiltonian. Equations (1.50) and (1.51) have provided the basis for several calculations on proton-hydrogen collisions. McCarroll (1961) calculated resonance charge transfer between the $1s$ states and included only one orbital on each nuclei. Lovell and McElroy (1965) extended the calculations to excitation and capture into the $2s$ -states. They used various combinations of $1s$ and $2s$ orbitals, with a total maximum of three, to investigate rates of convergence of the cross-sections. However the most extensive calculation of this type so far is that by Wilets and Gallaher (1966) who include all $n = 1$ and $n = 2$ states of A and B and check convergence by extending the calculation to $3s$ and $3p$ states for some selected impact parameters and energies. The change in the cross-sections with the addition of the $n=3$ states is small and although the solution would have appeared to have converged, no account has yet been taken of continuum states.

In an attempt to include effects due to continuum states, Gallaher and Wilets (1968) expanded the electronic wave function in terms of Sturmian functions. These functions form an infinite discrete and complete basis set without a continuum and the transition amplitudes are obtained by projection onto the hydrogenic states.

A completely different approach was proposed by Cheshire (1965). Using equations (1.43), he eliminated the B

coefficients by using closure, and then the calculation of the A amplitudes from the resulting second order equation would take implicit account of the complete set of rearrangement states. This closure approximation is discussed further in Chapter IV.

CHAPTER II

ELASTIC SCATTERING OF LITHIUM ION IN HELIUM

1. Introduction

The system Li^+ , He is sufficiently simple as to provide a testing ground for theoretical models of elastic ion-atom scattering. Data of Aberth and Lorents (1965) show that the inelastic component of the cross-section is less than 1% of the elastic component at an angle of 10° for an incident energy of 600 e.V. Therefore the system provides a ready comparison between theory and experiment without having to take inelastic effects into account.

The scattering predicted by some of the semi-empirical potentials (derived from experimental data) has been analyzed by Weber and Bernstein (1965) using a JWKB approximation for the phase shifts. The purpose of this present work is to extend this analysis to more recent semi-empirical potentials and more importantly, to the more accurate a priori potentials now available. In the regions where the JWKB is inaccurate, exact quantal phase shifts are obtained. Experimental measurements of differential scattering through angles greater than a given angle, $S(\theta)$, (Zehr and Berry, 1967), differential cross-sections, $I(\theta)$, (Aberth & Lorents, 1969) and the temperature variation of the mobility K (Hoselitz, 1941), are available for comparison. Atomic units are

used throughout except where otherwise stated.

2. The Radial Equation and Solutions

In the absence of inelastic processes the scattering of Li^+ by He may be described by the appropriate solution of the differential equation

$$\left[\frac{d^2}{dr^2} + k^2 - 2\mu V(r) - \frac{\ell(\ell+1)}{r^2} \right] u_\ell(r) = 0 \quad (2.1)$$

satisfying

$$u_\ell(0) = 0, \quad u_\ell(r) \underset{r \rightarrow \infty}{\sim} k^{-1/2} \sin(kr - \frac{1}{2}\ell\pi + \eta_\ell) \quad (2.2)$$

where η_ℓ is the phase shift, ℓ is the angular momentum quantum number, k is the relative momentum of the collision, μ is the reduced mass of the system and $V(r)$ is the interaction potential.

This equation can be solved numerically and the phase shift can be determined at large r . Extraction of the phase shift from the solution at a finite value of r , r_1 say, incurs an error since the effect of the non-vanishing potential for $r > r_1$ has not been accounted for. At large r the potential is slowly varying and a JWKB analysis has been used by Seaton and Peach (1962) and by Burgess (1963) to determine, to first and second order respectively, a correction factor to the solution at $r=r_1$ due to the long range tail of the potential, $r > r_1$. For large r , the interaction potential is

effectively the polarization potential of He written

$$V_{\text{pol}}(r) = -\frac{\alpha}{2r^4} \quad \text{a.u.} \quad (2.3)$$

where $\alpha = 1.384 \, a_0^3$, is the polarization of helium (see section 4).

If we write

$$u_\ell(r) \underset{r \rightarrow \infty}{\sim} \sin(\phi(r) + \eta_\ell),$$

the second order approximation (including terms up to r^{-3}) of $\phi(r)$ for a potential (2.3) as derived by Burgess is

$$\phi(r) = (k^2 r^2 - c)^{1/2} - \frac{1}{2} \ell \pi + \Theta - \frac{1}{8(k^2 r^2 - c)^{1/2}} - \frac{5c}{24(k^2 r^2 - c)^{3/2}} \quad (2.4)$$

with $c = \ell(\ell+1)$ and

where

$$\begin{aligned} \Theta &= \frac{(c+1/8)}{c^{1/2}} \arcsin \frac{c^{1/2}}{kr} + \frac{\alpha \mu (k^2 r^2 - c)^{1/2}}{8cr^2} \\ &\quad - \frac{\alpha \mu k^2}{8c^{3/2}} \arcsin \frac{c^{1/2}}{kr} \quad c > 0 \\ &= \frac{1}{8kr} - \frac{\mu \alpha}{12kr^3} \quad c = 0 \end{aligned}$$

The phase shift can now be determined to a high degree of accuracy without the necessity of continuing the step by step integration of the radial equation to the much larger distances required if only the first order asymptotic forms of the solution are used.

At sufficiently large energies (Munn, Mason and Smith, 1964), the JWKB approximation is valid and can be used to determine the phase shifts (eqn. (1.5)). These phase

shifts themselves can be replaced for large ℓ by the Jefferys-Born phase shift (eqn. (1.6)). At these large distances ($r \sim \ell/k$) the potential is given by (2.3) and the J-B phase shift is readily obtained in closed form

$$\eta_{\ell}^{\text{JB}} = \frac{\alpha \mu k^2}{2(\ell+1/2)^3} \frac{\pi}{4} \quad (\text{radians}) \quad (2.5)$$

3. Theoretical Prescription of Scattering Cross-Sections

The derivation of cross-sections in terms of infinite sums of phase-shifts is well known (Mott & Massey 1965) and the cross-sections required in the following analysis will be only stated here for the purpose of completeness.

The total elastic scattering cross-section is given by,

$$Q_{\text{el}}(k^2) = \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell+1) \sin^2 \eta_{\ell} \quad (a_0^2) \quad (2.6)$$

while the diffusion cross-section is

$$Q_{\text{d}}(k^2) = \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (\ell+1) \sin^2(\eta_{\ell} - \eta_{\ell+1}) (a_0^2). \quad (2.7)$$

The differential scattering cross-section at angle θ is

$$I(\theta) = \frac{1}{4k^2} (A^2 + B^2) \quad (a_0^2) \quad (2.8)$$

where

$$\begin{aligned} A &= \sum_{\ell} (2\ell+1) (\cos 2\eta_{\ell} - 1) P_{\ell}(\cos \theta) \\ B &= \sum_{\ell} (2\ell+1) \sin 2\eta_{\ell} P_{\ell}(\cos \theta) . \end{aligned}$$

By integration, the cross-section $S(\theta)$ for scattering outside a cone of semi-angle θ about the forward direction

$$S(\theta) = 2\pi \int_{-1}^{\cos\theta} I(\theta) d(\cos\theta) \quad (a_0^2). \quad (2.9)$$

The above infinite sums in practice have to be truncated and the number of phase-shifts giving an appreciable contribution is determined by the range, R , of the interaction and the momentum, $k=\mu v$. As will be seen in the next section, the range of the interaction potentials is of the order of $10a_0$.

Now $\ell_{\max} \sim Rk$, which means at the highest collision energy considered, $E \sim 250$ eV ($k=3 \times 10^2$ a.u.), approximately 3×10^3 phase shifts are required. However for extremely low energies of interest in mobility calculations, fewer than 10^2 phase shifts contribute to the cross-sections.

Finally the mobility, K , is determined from the diffusion cross-section Q_d ,

$$K = \frac{eD}{k_B T} \quad (\text{cm}^2 \text{ volt}^{-1} \text{ sec}^{-1}) \quad (2.10)$$

where T is the absolute temperature, k_B is the Boltzmann's constant, e is the ionic charge and D , the diffusion coefficient, is given by

$$D = \frac{3\pi^{1/2}}{16n} \left(\frac{2k_B T}{\mu} \right)^{1/2} \quad (2.11)$$

with

$$P = \int_0^{\infty} \exp(-x^2) x^5 Q_d(x) dx, \quad x^2 = \frac{\mu v^2}{2k_B T} \quad (2.12)$$

to first order (Dalgano et al, 1958) where n is the number density of the gas. We ignore the second order correction factors of the Chapman-Enskog theory (Dickenson 1968). The reduced mobility K' is that obtained with $n=2.98 \times 10^{19} \text{ cm}^{-3}$.

4. Li^+ -He Interaction Potentials

Several groups of workers have attempted to deduce an interaction potential for the ground state of LiHe^+ from one or other set of experimental measurements. Potentials derived from mobility data may be represented by that of Dalgano et al (1958),

$$V_1(r) = 37.10e^{-2.75r} - 0.695r^{-4}, \quad \text{for all } r. \quad (2.13)$$

Zehr and Berry (1967) used a classical model (Hoyt, 1939) to invert their data on $S(\theta)$ to obtain

$$V_2(r) = 13.60e^{-2.70r}, \quad 0.1 < r < 1.4a_0 \quad (2.14)$$

while Olson et al (1969) have deduced a potential

$$V_3(r) = 10.92e^{-2.28r} + 37.01e^{-10.79r} \quad 0.3 < r < 1.7a_0 \quad (2.15)$$

from the differential cross section measurements of Aberth and Lorents (1969) by a classical analysis with the aid of expansion formulae (F.T. Smith et al, 1966).

With the development of fast, large digital computers in the last few years, a priori calculations of the potential have become possible. Preliminary calculations for a restricted range of the internuclear separations ($0.2 < r < 1.4a_0$) have been made by Fischer (1968) and of the long range part ($2 < r < 8a_0$) by Schneiderman and Michels (1965). An outline of a more extensive calculation performed in the main by Kaufman and Sachs, and reported more fully by Catlow et al, 1969, covering all internuclear separations is now reported and results presented.

The calculations were of the Hartree-Fock-Roothaan type (Roothaan 1951) where the wave function for a closed shell species is a single determinant of the one-electron molecular orbitals (MO's) built up from the atomic orbitals centered on the atoms. The actual computations were carried out with the MOSES program (Sachs and Geller 1967) utilizing Gaussian basis functions centered on both atoms. Gaussian-type orbitals have the same structural form as Slater-type orbitals except the exponential, $e^{-\zeta r}$, in the latter is replaced by a Gaussian $e^{-\alpha r^2}$. There is no denying that the Gaussian-type orbitals are far inferior basis functions to the STO's in representing atomic orbitals but their advantage lies in the contrasting simplicity of the evaluation of molecular integrals over Gaussian functions.

In Table 2.1 are listed the Gaussian exponents used in the present calculations. As a check on the necessity of

including p orbitals in the basis set to allow for polarization, E_{HF} of LiHe^+ was calculated using only the 10^5 exponents on each atom.

In spite of the fact that $E_{\text{HF}}(\text{LiHe}^+) (10^5; 10^5)$ ($=10.09832145$ a.u.) at $r=3.75a_0$, was for ordinary purposes quite close to the $E_{\text{HF}}(\text{LiHe}^+) (10^5 6^p; 10^5 6^p)$ ($=10.10022048$ a.u.) at the same r , it failed completely when calculating the polarization potential, the discrepancy of 0.00290598 a.u. being actually larger than the entire calculated attractive polarization potential of -0.002363 a.u.

The calculated quantity is the energy $E_{\text{mol}}(r)$ of the ground state of the LiHe^+ molecule. It is related to the scattering potential $V(r)$ by

$$V(r) = E_{\text{mol}}(r) - E_0(\text{Li}^+) - E_0(\text{He}) \text{ a.u.} \quad (2.16)$$

where $E_0(A)$ is the ground state energy of atom (or ion) A. We take the Hartree-Fock values of $E_0(\text{Li}^+)$, $E_0(\text{He})$ generated with the same basis set, so much of the small error due to omission of the correlation energy in the MO-SCF procedure is subtracted out. The program becomes impractically time consuming for $r < 0.1a_0$ and an extrapolation to the spectroscopic value of the united atom energy is made. As Fischer (1968) has already pointed out the $(1\sigma)^2 (2\sigma)^2$ ground state configuration of LiHe^+ goes over in the united atom limit to the $(1s)^2 (2s)^2$ ground state of B^+ .

At moderate values of r , ($5 < r < 8a_0$) the calculated

potential $V(r)$ is closely fitted by the polarization potential (2.3) which is then used for $r > 8a_0$.

The potential of Fischer (1968) is also calculated in the MO-SCF model with Gaussian basis sets and is indistinguishable from the present calculations in his range of values. The potential given by Schniederman & Michels (1965) is not as close a fit to (2.3) for $r > 5a_0$ as the present results.

An independent calculation of the interaction potential by Junker & Browne (1969), denoted by $V_4(r)$ here, is in progress and preliminary results are available for comparison. Table 2.2 shows that Junker's total separated atom energy is closer to the spectroscopic value than the present work but that the latter agrees well with SCF values of Roothaan et al.

$V(r)$ at all r , and though both have a minimum near $r=3.75a_0$, the depth of the minimum of $V(r)$ (-0.002363 a.u. ≈ -0.064 e.V.) is considerably larger than their value (-0.0011 a.u. ≈ 0.030 e.V.). For $r>5a_0$, $V(r)$ is much closer to the polarization potential than is Junker and Browne's potential. However the differences between the two potentials are small.

The potentials $V_2(r)$ and $V_3(r)$ are compared with the results of the quantal calculations in the core region $0<r<2.5a_1$ in fig. 2.1. Neither of the semi-empirical potentials is sufficiently repulsive at small r ($r<1.0a_0$), though the Olson et al potential agrees well with the quantal calculations in the range $1.0<r<2.0a_0$. Neither of these potentials produce binding so no comparison is made with the quantal calculations for larger r . Olson et al point out that their absolute values are uncertain by $\pm 25\%$, so there is no disagreement in magnitude with our potential, however their slope is too shallow.

The potential $V_1(r)$ deduced from mobility data does show a minimum and has the correct long range behaviour. For $r>1a_0$ it is in excellent agreement with the potential presented here.

5. Numerical Evaluation of Phase Shifts and Phase Shift Sums

In general the phase shifts for a given potential at a centre of mass collision energy E_{cm} (momentum $k = (2E_{cm}\mu)^{1/2}$) were evaluated in the JWKB approximation (1.1) using the modified Clenshaw-Curtis quadrature method of Kennedy

FIGURE 2.1

Quantal and Semi-Empirical Potentials.

and Smith (1967).

If we write

$$F(r) = \left[1 - V(r)/E_{cm} - b^2/r^2 \right]^{1/2} \quad (2.17)$$

where b is the impact parameter, the JWKB phase shift (1.1) can be approximated by

$$\begin{aligned} I_N = & \frac{kr_m r_o}{2} \sum_{s=0}^{N-1} h_s^N F(r_m/\cos\theta_1) \sin\theta_1/\cos^2\theta_1 \\ & + \frac{kb\pi}{4} \sum_{s=1}^{N-1} h_s^N \left[F(b/\cos\theta_2) - \sin\theta_2 \right] \sin\theta_2/\cos^2\theta_2 \end{aligned} \quad (2.18a)$$

if $b \geq r_m$, and

$$\begin{aligned} I_N = & \frac{k(r_m + \alpha)\pi}{4} \sum_{s=1}^{N-1} h_s^N \left[F(r_3) - (1 - b^2/r_3^2)^{1/2} \right] \sin\theta_2/\cos^2\theta_2 \\ & + k \left[b \arccos(b/r_m) - (r_m^2 - b^2)^{1/2} \right] \end{aligned} \quad (2.18b)$$

if $b < r_m$. In these formulae

$$\begin{aligned} \theta_1 &= \frac{1}{2}r_o \left[1 + \cos\pi s/N \right], \quad \theta_2 = \frac{1}{4}\pi \left[1 + \cos\pi s/N \right] \\ r_o &= \arccos(r_m/b), \quad r_3 = (r_m + \alpha)/\cos\theta_2 - \alpha \end{aligned}$$

and h_s^N are the weights given by

$$h_s^N = \frac{2(-1)^s}{N^2 - 1} + \frac{4}{N} \sin \frac{s\pi}{N} \sum_{r=1}^{\frac{1}{2}N} \frac{\sin \frac{[(2r-1)s\pi/N]}{2r-1}}{2r-1}. \quad (2.19)$$

The constant α is a scaling factor and was taken to be equal to a_0 . Results of Kennedy and Smith for a L-J potential at three energies were reproduced to five decimal places with maximum $N=64$.

Hence in the present calculations, N initially took the value 16, and was increased in two steps to a maximum of 64 and the criterion for convergence was that the proportional increase in the new value of I_N was less than 10^{-4} .

Congergence was poor for $k < 3$ a.u. (0.02 e.V.) so in this region the radial equation (2.1) was solved by Numerov's method. The solution was started at the point $r=s$ where

$$V_{\text{eff}}(s, \ell) = V(s) + \frac{\ell(\ell+1)}{s^2} = 150 \text{ a.u.} \quad (2.20)$$

with initial conditions

$$u_\ell(s) = 0, \quad u_\ell(s+h) = 10^{-30}$$

and the step length, h , equal to 5×10^{-3} .

Throughout the energy range for which Numerov's method was employed ($k < 3.5$ a.u., see below) the solution was insensitive to the choice of the starting point criterion (2.20) or its starting values. This is illustrated in Table 2.4 where phase shifts derived with different varying initial conditions are compared. The phase shift was determined from the asymptotic form of the solution by the Burgess procedure (2.4), the criterion for convergence being that ten consecutive values of η_ℓ extracted at $r+2mh$ ($m=0,9$) should agree to 2×10^{-3} radians.

(Identical values are obtained if the second initial
value of the solution is taken as $u_l(s + h) = 1$)

At large ℓ , for all k , the JB approximation (2.5) to the phase shift is adequate and was adopted with η_{ℓ}^{JB} agreed with η_{ℓ} or $\eta_{\ell}^{\text{JWKB}}$ to within 0.01 radians. The phase shift sums were truncated when the phase shift became less than 0.01 radians.

The energy at which the JWKB approximation became inadequate for at least some value of ℓ was estimated from Munn, Mason and Smith's results and at different neighbouring energies results from both the JWKB procedure and the Numerov method were compared. For $k > 3.5$ agreement was good for both phase shifts and the summed cross-sections, and this shown for the latter in Table (2.5).

TABLE 2.5

Comparison of exact and JWKB cross-sections (a_0^2) in the region near $k=3.5$ for the potential $V(r)$

6.0	1.051, -1	715.0	717.2	58.04	57.79

It is estimated that the quantal phase shifts are correct to 10^{-4} radians and the JWKB phase shifts to 10^{-2} radians.

Typical low energy phase shifts for $\ell < 36$ are shown in fig. 2.2 and for $k < 2.0$ discontinuities show the occurrence of classical orbiting and the presence of resonance bound states. These jumps in the phase shifts occur when there is a loss of a zero in the solution and this is illustrated in fig. 2.3 for $k = 2.6 \text{ a.u.}$ The zero energy limit of the s-wave phase shift was found to be 7π and if Levinson's theorem can be applied the potential can support seven bound states.

All the above preliminary results were calculated using the SCF-MO potential, $V(r)$, which possesses both a short range repulsive part and a long range attractive part. Other potentials of this form will predict phase shifts exhibiting the same qualities as above. It is well known that the positive phase shifts arise from the attractive well of the potential whereas the repulsive region predicts negative phase shifts. Purely monotonic repulsive potentials (eg. V_2 , V_3) produce no positive phase shifts and the features such as orbiting and glory scattering cannot be seen. At low energies where the positive phase shifts dominate the scattering there is a substantial disagreement in the total cross-sections and transport cross-sections predicted by the two types of potentials. This will be discussed later.

The computer code included six potentials for the $\text{Li}^+ - \text{He}$ system which were the SCF-MO potential, Junker-Browne (1969), Zehr-Berry (1967), Olson et al (1969), Dalgarno et al (1958) and Weber and Bernstein's V_4 (1965). The first two

 $\ell = 19$  $\ell = 20$  $\ell = 23$ 

Radial Wave Function

Illustrating phenomenon of tunneling through the centrifugal barrier for $k = 2.6$ a.u. (The amplitudes are unrelated)

were non-analytic and have been given in table (2.3). The values of the potential at intermediate points was obtained using Aitken-Lagrange interpolation routines. At small internuclear distances $r < 0.2$ a.u. where these routines were inadequate, the potential was given by a crude analytic fit to the small internuclear values and at $r=0$ to the ground state of $B^+(1s^2 2s^2, ^1S_0)$.

$$V(r) = 14.5r - 14.26 + \frac{6}{r} \quad (\text{a.u.}) \quad 0 < r < 0.2a_0. \quad (2.21)$$

The code calculated total and diffusion cross-sections (2.6, 2.7) and also included the option of evaluating differential cross-sections (2.8) at specified angles. Legendre polynomials when required were generated by the usual recursion relation until $\ell=300$ when their asymptotic form for large ℓ

$$P_\ell(\cos\theta) = \left(\frac{2}{\ell\pi\sin\theta} \right)^{1/2} \left[\left(1 - \frac{1}{4\ell} \right) \cos[(\ell+1/2)\theta - \pi/4] + \frac{1}{8\ell} \cot\theta \sin[(\ell+1/2)\theta - \pi/4] \right] \quad (2.22)$$

was used (Hobson 1931).

The code also evaluated $S(\theta)$, (2.9), from $I(\theta)$ using a Simpson's integration. Because of the absence of structure in the differential cross-sections ($E_{cm} > 10 \text{ e.V.}$) only 150 Simpson intervals were required in the range $0 \rightarrow 180$ degrees.

The computations were performed on the N.U.M.A.C.

I.B.M. 360/67 computer of the Universities of Newcastle and Durham. The time required for one phase shift, varied but an estimated average value is of the order of 400 JWKB phase-shifts and 60 quantal phase-shifts per minute. The interpolation routines for the non-analytic potentials were found to be time consuming and total run times for these potentials could be increased by as much as a factor of three. Although in this present work the speed of the computer allowed the non-analytic potential to be used throughout the energy range, it was found that except in the low energy region where the shape of the potential is important, these potentials could be adequately represented by good analytic fits.

6. Results

The computer codes were checked by reproducing (i) the JWKB phase shifts of Kennedy and Smith (1967), and (ii) the differential cross sections of Weber and Bernstein (1965) for their potential $V_4(r)$ shown in their figures 6 and 7.

Differential cross-sections $I(\theta)$ were computed for potentials V , V_2 , V_3 and V_4 at three centre of mass energies corresponding to the measurements of Aberth and Lorents (1969) and also at two lower energies. Results are shown in figs. 2.4 a,b,c.

Excellent agreement is obtained with the classical results of Olson et al (1967) for the potentials V_2 & V_3 (not shown). The agreement with the experimental results as in the

FIGURE 2.4a.

Elastic Differential Cross-Sections

The circles are samples of the experimental points of Aberth and Lorents (1969). The full curves $i = 1, 2, 3$, are theoretical values calculated semi-classically using the potentials $V(r)$, $V_2(r)$ and $V_3(r)$ respectively.

FIGURE 2.4b.

Elastic Differential Cross-Sections.

FIGURE 2.4c

work of Olson et al, is also excellent except at the large angles for each energy where the calculated cross-sections are consistently larger. The predicted values of $S(\theta)$, discussed in more detail below, also agree well with the observed values of Zehr and Berry (1967). However any reasonable extrapolation to large angles of the Aberth and Lorents measurements gives values of $S(\theta)$, $\theta > 70^\circ$ lying substantially below the Zehr-Berry data and inconsistent with them.

At $E_{cm} = 3.64 \text{ e.V.}$ the differential cross-section from the SCF-MO potential shows some structure although this cannot be seen in fig. 4a. More detailed results at centre of mass energies 1.33, 2.65 and 3.64 e.V. are shown in figs. 2.5 for $V(r)$, $V_2(r)$ and $V_4(r)$. Considerable structure is predicted by the SCF-MO potential and the Junker-Browne potential at centre of mass angles in the range $5^\circ < \theta < 15^\circ$. The Zehr-Berry potential, which is purely repulsive, gives a monotonic decreasing differential cross-section and no evidence of structure. The larger number of phase shifts contributing to $I(\theta)$ at small angles ($\theta < 5^\circ$) lead to convergence difficulties with the code and results in the near forward direction are not shown.

The structure predicted at $E_{cm} = 3.64$ is not seen in the published experimental data of Aberth and Lorents (1969). However the amplitude of the oscillations are of the same magnitude as the random error associated with the experimental

FIGURE 2.5a.

FIGURE 2.5b.

work. A more detailed experimental investigation of the energy region below 10e.V. at angles less than 15° would be of interest.

Calculated values of $S(\theta)$ predicted by the SCF-MO potential and the Zehr-Berry potential are compared at five laboratory energies with the experimental measurements of Zehr and Berry in fig. 2.6. The two sets of results are equally consistent with the data. The slope of the experimental points is less steep than the theoretical curves at small angles and in this region better agreement is obtained with the Zehr-Berry results. At larger angles the SCF-MO potential results are closer to the experimental points.

Total cross-sections $Q_{e1}(k^2)$ and diffusion cross-sections $Q_d(k^2)$ are given in detail in the appendix for the SCF-MO and the Junker-Browne potential at energies $k=0.02$ (0.01) 0.12(0.02) 1.0 (0.1) 4.0 (0.5) 20.0 (5.0) 100.0. It is readily seen that for the greater part of the low energy range ($E_{cm} < 10\text{e.V.}$) the Junker-Browne cross-sections lie substantially below those predicted by the SCF-MO potential, by as much as a factor of three or four at the lowest energies. This is because the former's potential well is shallower, having only half the depth of the SCF-MO potential well, and at low energies the long range attractive part of the potential dominates the collisions. The discrepancies in the cross-sections increase for the monotonic repulsive potentials. Total cross-section results for the SCF-MO potential and the

monotonic repulsive potentials of Zehr and Berry (V_2) and Olson et al (V_3) are compared at a few energies in Table 2.6. It can be seen that energies of the order of 5.10^2 greater than the well depth (0.05e.v.) are required before the well becomes negligible.

Bernstein (1962, 1963) has analyzed total cross-sections and related the number of glory scattering undulations, about the random phase approximation, semiclassically to the number of bound (vibration-rotation) states that the potential supports. The SCF-MO total cross-section is compared with the SSL approximation (Bernstein and Kramer, 1963) in fig. 2.7 and is seen to have nine undulations for $k > 0.02$ a.u. ($E_{cm} = 1.16 \times 10^{-6}$ e.V.). The two maxima at $k = 0.03$ and $k = 0.34$ arising from orbiting or rainbow scattering ($\ell = 2$ and 7 respectively) while the remaining seven correspond well with the zero energy limit of the s-wave phase-shift which was found to be 7π . If Levinson's theorem applies, this indicates the occurrence of seven bound vibrational states. A further estimation of the number of bound states, n , the SCF-MO potential could support was given by the JWKB approach in which

$$n + \frac{1}{2} = \frac{1}{\pi} \int_{r_m}^{\infty} (2\mu |V(r)|)^{1/2} dr \quad (2.23)$$

where r_m is the classical turning point and we assume there are no bound states at zero energy. A hand computation gives the rhs of (2.23) to be equal to 7.59, consistent with Levinson's

theorem prediction and the number of glory undulations in the total cross-section. This confirms in this case Bernstein's (1966) conjecture that "the observation of m maxima in the elastic cross-section implies the existence of at least m vibration states" and Munn et al's (1964) criticism that the undulations due to rainbow scattering must not be counted.

The diffusion cross-section for the SCF-MO potential is shown in fig. 2.8 and compared with the polarization diffusion cross-section. The latter is obtained from the polarization potential (2.3) and the JB approximation. It can be evaluated analytically and is given by

$$Q_{d.pol}(k) = \frac{577.3}{k} a_o^2 \quad (2.24)$$

The SCF-MO diffusion cross-section has considerable structure which hasn't a simple interpretation. For small k the successive maxima are separated by as little as $k=0.16$ corresponding to a temperature variation of less than $1^\circ K$. In averaging over Q_d to obtain the mobilities most of the structure is removed.

The reduced mobility, K' , as a function of temperature in the range $10^\circ K < T < 600^\circ K$ is shown in fig. 2.9 for the SCF-MO potential and the Junker-Browne potential. The results obtained from the former are consistent within the limits of experimental error with the measurements of Hoselitz (1941) over the entire range of temperatures. They do not approach

FIGURE 2.8

FIGURE 2.9

The Mobility of Lithium Ions in Helium

the Langevin limit (Langevin, 1905) ($30.6 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$) as $T \rightarrow 0$ but drop sharply below it due to the mean value of Q_d being larger than $Q_{d, \text{pol}}$ in the temperature range of interest (see fig. 2.9). At 20°K the equivalent energy is $\sim 0.17 \times 10^{-2} \text{ e.V.}$ and the integral (2.12) has a lower limit corresponding to $1.1 \times 10^{-6} \text{ e.V.}$

It was noted earlier (section 4) the excellent agreement between the SCF-MO potential and the potential of Dalgarno et al (1958). Dalgarno et al derived their potential by trial and error fits to the Hoselitz mobility data using a semiclassical approach for the cross-sections. They reduced the data by a factor of $1/1.08$ (which they attributed to a systematic error in Hoselitz's experiment) and ignored the points at $T=20^\circ\text{K}$ and 78°K to allow their fitted curve to have the Langevinian zero energy limit. In the light of these adjustments, the two calculated mobilities show remarkable agreement considering the diversity of the methods used.

The mobility results predicted by the Junker-Browne potential lie much higher in the temperature range shown.

7. Conclusions

An accurate SCF-MO interaction potential for LiHe^+ ($1\sigma^2 2\sigma^2$) over the range $0.1 < r < 8.0$ as is presented and scattering cross-sections of Li^+ by He have been calculated and compared with experiment.

Differential cross-sections $I(\theta)$ agree well with the experimental measurements of Aberth and Lorents (1969) for angles $< 70^\circ$. For angles greater than 70° the measurements are too low and become inconsistent with the calculated values and the measurements of $S(\theta)$ by Zehr and Berry (1967). It is of interest to note that analysis of (He^+, He) scattering by Boyle (PhD Thesis Queen's University, Belfast, 1969) yields results, from a modified quantal potential, which are inconsistent with the measurements of Lorents, Aberth and Hesterman (unpublished) for $E_{\text{cm}} > 100$ eV and $\theta > 40^\circ$. Using Bernstein's semiclassical relationship, the undulations in the total cross-section for the SCF-MO potential indicate that the potential supports at least seven bound vibrational states. A similar analysis for the Junker-Browne potential shows it supports three such states. It was seen that the potential well depth 0.054 e.V. had a considerable effect on the magnitude of the total cross-section up to energies of the order of 25 e.V.

There are no direct measurements of the diffusion cross-section Q_d but the results from the SCF-MO potential correctly reproduce the observed mobility of Li^+ ions in He both in magnitude and temperature variation. The mobility of the shallower Junker-Browne fails to do this.

These results together with the mobility results point to a well depth of not less than 0.05 e.V. Also it is estimated that for $2.5 < r < 8.0 a_0$ the SCF-MO potential should

be correct to within 0.05 e.V.

It has been seen that the differential cross-sections above 10 e.V. are comparatively insensitive to the choice of interaction potential; all the potentials considered being equal consistent with the experimental points. The mobility data can be used as a criterion for comparing the relative merits of the long range parts of the potentials. However results of a more detailed experimental investigation, if feasible, of differential cross-sections for energies less than 10 e.V. and at angles less than 15° would provide a stringent test for potentials.

APPENDIX

Total Elastic and Diffusion Cross-Sections for the
SCF-MO and Junker-Browne Potentials.

CHAPTER III

A CLASSICAL MODEL FOR PROTON AND ELECTRON IMPACT IONIZATION

1. Introduction

Although, as discussed in Chapter I, classical models of ionization are in reasonable accord with experiment, they consistently predict cross-sections that are too high at moderate energies and fall off too fast at high energies. In an attempt to partially correct this failing, we will consider a model for ionization of atoms in which the velocity distribution of the atomic electron is given by the analytic Hartree-Fock wave functions of Roothaan and co-workers.

The model is essentially that of Gryzinski (1959). That is to say that the electrons are regarded as indistinguishable and interact separately with the incident particle. Also the binding forces between the bound electrons and target nucleus are switched off during the collision. It is thus a classical binary encounter impulse approximation.

We consider the case of an incident particle of mass m_2 and velocity v_2 impinging on a bound electron with velocity v_1 . In the following analysis we shall use atomic units throughout, except for energies which will be expressed in rydbergs. It is convenient to adopt dimensionless variables s , t defined as

$$s^2 = v_2^2/v_0^2 \quad t^2 = v_1^2/v_0^2 = E_1/u \quad (3.1)$$

where $u=v_0^2$ is the ionization potential in rydbergs. Using these dimensionless variables Stabler's (1964) ionization cross-sections for electron impact (eqn. (1.15)) become

$$\begin{aligned} u^2 Q(s,t) &= \frac{4}{3s^2} \frac{2(s^2-1)^{3/2}}{t} (\pi a_0^2) \quad 1 \leq s^2 \leq t^2+1 \\ &= \frac{4}{3s^2} \left[2t^2+3 - \frac{3}{s^2-t^2} \right] (\pi a_0^2) \quad s^2 \geq t^2+1 \end{aligned} \quad (3.2)$$

and from Vriens (1967) for proton impact (eqn. (1.16))

$$\begin{aligned} u^2 Q(s,t) &= \frac{4}{s^2} \left[1 + \frac{2t^2}{3} - \frac{1}{4(s^2-t^2)} \right] (\pi a_0^2) \quad 1 \leq 4s(s-t) \\ &= \frac{2}{s^2 t} \left[\frac{1}{4(s+t)} + t + \frac{2}{3} (2s^3 + t^3 - (1+t^2)^{3/2}) \right] (\pi a_0^2) \\ &\quad 4s(s-t) \leq 1 \leq 4s(s+t) \end{aligned} \quad (3.3)$$

$= 0, \text{ otherwise.}$

$Q(s,t)$ is the ionization cross-section for a projectile of energy $m_2 s^2 u$ rydbergs ($m_2=1$ for electron impact) incident on a bound electron (binding energy in rydbergs) of kinetic energy $t^2 u$ rydbergs. Hence the total ionization cross-section for the projectile incident on a target atom is from eqn. (1.17)

$$Q(s) = \sum_{n,\ell} N_{n\ell} \int_0^\infty f_{n\ell}(t) Q(s,t) u^{1/2} dt \quad (3.4)$$

where the summation is over the outer subshells of the target atom, $f_{n\ell}(t)$ is the velocity distribution of one electron in the subshell and $N_{n\ell}$ is the number of bound electrons in the subshell.

2. Velocity Distribution for Atomic Electrons

The velocity distributions are obtained from Fourier transforms of Hartree-Fock wave functions. The wave functions are from Roothaan et al (1960, 1962, 1963) and Bagus (1966) and are of the form

$$\psi_{n\ell m}(\underline{r}) = \left[\sum_i c_i R_{in}(r) \right] Y_{\ell m}(\theta_r \phi_r) \quad (3.5)$$

where $Y_{\ell m}$ are spherical harmonics, R_{in} are Hartree-Fock radial functions and c_i are normalization constants. In momentum space the wave function is

$$\psi_{n\ell m}(\underline{p}) = \frac{1}{(2\pi)^{3/2}} \int \psi_{n\ell m}(r \theta_r \phi_r) e^{i\underline{p} \cdot \underline{r}} d\underline{r} \quad (3.6)$$

where \underline{p} describes the position in momentum space. Now we employ two well known properties of spherical harmonics (Messiah, 1961)

$$\int_0^{2\pi} \int_{-1}^1 Y_{\ell m}^* Y_{\ell' m'} d\phi d(\cos\theta) = \delta_{mm'} \delta_{\ell\ell'} \quad (3.7)$$

$$e^{i\underline{p} \cdot \underline{r}} = 4\pi \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} i^{\ell} j_{\ell}(pr) Y_{\ell m}(\theta_p \phi_p) Y_{\ell m}^*(\theta_r \phi_r) \quad (3.8)$$

where j_ℓ is the spherical Bessel function and the subscripts on the angular variables indicate the vector to which they refer. Hence the momentum space wave function readily reduces to

$$\psi_{n\ell m}(\underline{p}) = \frac{1}{(2\pi)^{3/2}} \int_0^\infty \left(\sum_i c_i R_{in}(r) \right) 4\pi i^\ell j_\ell(pr) Y_{\ell m}(\theta_p, \phi_p) r^2 dr \quad (3.9)$$

The velocity distribution, which in atomic units is identical to the momentum distribution for electrons, in the " $n\ell$ " subshell of the atom is given as

$$\rho_{n\ell}(\underline{v}_1) = \frac{1}{(2\ell+1)} \sum_{m=-\ell}^{\ell} \psi_{n\ell m}^* \psi_{n\ell m} \quad (3.10)$$

Using (3.9) in (3.10)

$$\rho_{n\ell}(\underline{v}_1) = \frac{1}{2\pi^2} \left| \int_0^\infty (\sum_i c_i R_{in}) j_\ell(v_1 r) r^2 dr \right|^2 \quad (3.11)$$

Now

$$\rho_{n\ell}(v_1) = \rho_{n\ell}(\underline{v}_1) \quad (3.12)$$

and hence the required distribution function for equation (3.4) is

$$f_{n\ell}(t) = 4\pi t^2 u \rho_{n\ell}(u^{1/2} t) \quad (3.13)$$

It is easily seen that the correct normalization of the wave functions require that

$$\int_0^{\infty} f_{n\ell}(t) u^{1/2} dt = 1 \quad (3.14)$$

for all n, ℓ

The wave functions of Roothaan et al and Bagus can be written as in (3.5) with the radial functions of the form

$$R_{in}(r) = (2n!)^{-1/2} (2\zeta_i)^{n+1/2} r^{n-1} e^{-\zeta_i r} \quad (3.15)$$

and c_i, ζ_i are tabulated constants. The velocity distribution then reduces to a sum of elementary integrals $I_{in\ell}$ of the form

$$I_{in\ell} = c_i (2n!)^{-1/2} (2\zeta_i)^{n+1/2} \int_0^{\infty} r^{n+1} e^{-\zeta_i r} j_{\ell}(v_1 r) dr \quad (3.16)$$

which can be evaluated in closed form (Dwight 1964)

3. Results & Discussion

Cross-sections for inner and outer shell ionization of He, Li, O, N and Ne by both electron and proton impact are presented and in a few cases and compared with Born calculations of Peach (1968) and experiment.

The integral (3.4) over the velocity distribution of the bound electron was performed numerically by Gauss and Gauss-Laguerre quadratures. The integrand is smoothly varying and convergence is readily attained with a maximum of 24 abscissa. The normalization of the Hartree-Fock wave functions was checked by performing integrations of the form

(3.14). Finally the computer code was checked by reproducing previously published ionization cross-sections for hydrogen (Kingston 1966a, McDowell 1966).

For electron impact, three formulations of ionization cross-sections were calculated and compared. Q_1 was obtained from (3.4) with δ -function velocity distribution. A Hartree-Fock distribution in (3.4) produced a cross-section Q_2 , which was subsequently modified, Q_3 , by taking

$$f(t) = 0 \quad t > s$$

That is considering only collisions in which the incident electron is the faster of the two (Kingston 1966). This agrees with the procedure used in a quantal calculation when exchange is neglected (Peterkop 1961). In the case where the ground configuration of the residual ion gives rise to more than one electronic state (eg O^+ , N^+), an average ionization potential (Slater 1960) is used. Results at various energies are given for the outer shells of He, Table 3.1 and N, Table 3.2. It is readily seen that in going from Q_1 to Q_3 the maximum value of the cross-section is reduced and its position is moved to higher energies. In fact the maximum of Q_3 is 25% lower than Q_1 in Tables 3.1, 3.2 and this is typical of other cases considered. At high energies Q_2 and Q_3 lie above Q_1 . As will be seen below, these features tend to increase the agreement of the calculated cross-section with experiment.

* Only outer shell contribution.

A sample of ionization cross-sections (Q_3 for electron impact, Q_2 for proton impact) are compared with experiment in figures 3.1-3.5.

(Results for helium given previously (Catlow and McDowell 1967) are incorrect). For electron impact on nitrogen, Kieffer & Dunn (1966) think the cross-sections of Peterson (1964) are too large and Smith's (1962) values are to be preferred. If this is the case, the classical results are considerably better than the Born calculations of Peach (1968). In the case of electron ionization of oxygen, although both classical and quantal calculations are in close agreement with the experimental results of Boksenberg (1961) in the energy range shown, the experimental results of Rothe et al (1962) (not shown for the sake of clarity) almost reproduce the points of Fite and Brackmann (1959). This together with the situation for nitrogen would tend to suggest that both the calculations and Boksenberg's results are too high.

The results for neon produce the worst comparison with experiment of the systems considered. This was to be expected as neon is an inert gas with a complete outer shell of six 2p electrons and is not a system to which a binary encounter impulse approximation is really applicable. However these results are approximately 25% lower than those presented by Garcia et al (1968) who used a δ -function velocity distribution for the atomic electrons. It is noticeable that the quantal calculations also fail to an extent for this system.

FIGURE 3.2

Electron Impact Ionization of Atomic Nitrogen.

FIGURE 3.3

FIGURE 3.4
Proton Impact Ionization of Atomic Helium.

The classical cross-section falls off faster than the quantal cross-section at high energies, although this inherent deficiency in the classical model is not as apparent for electron impact if Q_3 is considered.

Comprehensive tables (3.3-3.7) of cross-sections for inner and outer shell ionization are given below. In the table headings $Q(n,\ell)$ is the ionization cross-section for the loss of an " $n\ell$ " electron from the atom. For high energies, proton and electron cross-sections at the same velocity agree closely.

4. Conclusions

Cross-sections for inner and outer shell ionization of He, Li, N, O and Ne by electron and proton impact, as calculated in a classical binary encounter impulse model, have been presented. It was found that cross-sections obtained with a Hartree-Fock velocity distribution for the atomic electrons were as much as 25% lower at their maximum values than corresponding cross-sections using a δ -function distribution, and hence in better agreement with experiment.

Apart from neon, ionization cross-sections for the atoms considered were at most a factor of 2 in disagreement with experiment and for the most part compared favourably with quantal Born calculations. For systems such as neon the model seems unsuitable.

CHAPTER IV
THE CLOSURE APPROXIMATION FOR EXCITATION
OF ATOMIC HYDROGEN BY PROTON IMPACT

1. Introduction

Several attempts have been made in recent years to include continuum intermediate states in theoretical studies of ion-atom collisions. In particular the Sturmian expansion method of Gallaher & Wilets (1967) and the impulse approximation (Coleman & Trelease (1968) and earlier work referred to therein) take partial account of the continuum in both direct and rearrangement processes. The angular momentum expansion of Cheshire & Sullivan (1967) includes all continuum states of angular momentum <1 for direct processes.

Cheshire (1965) suggested an alternative treatment of the continuum, within the impact parameter model, for proton-hydrogen atom collisions. In this present work we apply it to the process.

Atomic units will be used throughout.

2. The Closure Approximation

The notation and preliminary results of Chapter I (section 4) will be used. Within the impact parameter model, the total electronic wave function is expanded, in turn,

using travelling orbitals about the atomic nucleus, A, and then similarly about the incident proton B

$$\psi = \phi^A_A \quad (4.2)$$

$$\psi = \phi^B_B \quad (4.3)$$

The time variation of the matrices A, B are described by the coupled equations (1.43)

$$\frac{dA}{dt} = i(\phi^A | V_B | \phi^B) B \quad (4.4)$$

$$\frac{dB}{dt} = i(\phi^B | V_A | \phi^A) A \quad (4.5)$$

A truncation of both equations is generally necessary. If however the B coefficients are eliminated between (4.4) and (4.5) by using closure before truncation, then the A amplitudes may be calculated with implicit account of the complete set of rearrangement states. This is the purpose of the closure approximation.

A detailed derivation of the approximation is given by Cheshire (1965), and also by Coleman & McDowell (1969), and will not be reproduced here. The elimination of the B coefficients from (4.4) and (4.5) gives rise to an infinite set of second orders coupled differential equations,

$$\frac{d^2 A}{dt^2} - i(\phi^A | V_B T_B V_B^{-1} | \phi^A) \frac{dA}{dt} + (\phi^A | V_B V_A | \phi^A) A = 0 \quad (4.6)$$

Now

$$V_B T_B V_B^{-1} = -i \frac{d}{dt} \ln V_B + \frac{1}{2} V_B^2 + V_B^{-1} V_A \quad (4.7)$$

(Coleman and McDowell, 1969) so that (4.6) is of the form

$$\ddot{A} + G\dot{A} + HA = 0 \quad (4.8)$$

with

$$G = -\frac{d}{dt} (\phi^A | \ln V_B | \phi^A) - \frac{i}{2} (\phi^A | V_B^2 | \phi^A) - i (\phi^A | V_B^{-1} V_A | \phi^A) \quad (4.9)$$

$$H = (\phi^A | V_B V_A | \phi^A)$$

Equation (4.8) is solved with boundary conditions (1.29),

$$a_n = \delta_{np} \exp \left[-\frac{i}{v} \ln(vR - v^2 t) \right] \quad (4.10)$$

and the transition probability to state q is given by

$$P_{p,q}(\rho, v) = |a_q(+\infty)|^2 \quad (4.11)$$

where ρ is the impact parameter and v is the velocity of the collision. The required cross-section is

$$Q_{pq}(v) = 2 \int_0^\infty \rho P_{pq}(\rho v) d\rho \quad (\pi a_0^2) \quad (4.12)$$

3. Analysis

In the present work, the set of equations (4.8) was truncated and only two coefficients corresponding to the 1s and 2s states were retained. Associated variables will be

subscripted by 1 & 2 respectively.

The unitary transformation

$$\begin{aligned} a_1 &= \alpha_1 e^{i\eta} \\ a_2 &= \alpha_2 e^{-i\epsilon t + i\eta t} \end{aligned} \quad (4.13)$$

is applied to (4.8) where

$$\eta = -\frac{i}{v} \ln(vR - v^2 t) = i \int_{-\infty}^t \frac{1}{R} dt$$

and

$$\epsilon = \epsilon_2 - \epsilon_1.$$

This removes the time dependant phase factors from the matrix elements and the logarithmic phase factor from the boundary condition (4.10), so that the equations (4.8) become

$$\ddot{\alpha}_i + \sum_{j=1}^2 G'_{ij} \dot{\alpha}_j + \sum_{j=1}^2 H'_{ij} \alpha_j = 0 \quad (4.14)$$

with the boundary conditions

$$\alpha_i(t) \xrightarrow{t \rightarrow -\infty} \delta_{i1} \quad (4.15)$$

Explicit forms of G' and H' are given in the appendix and it can be seen that they involve only the basic matrix elements

$$\begin{aligned} P_{ij} &= (\phi_i | \frac{1}{XS} | \phi_j) \\ L_{ij} &= (\phi_i | \ln s^{-1} | \phi_j) \end{aligned} \quad (4.16)$$

$$Q_{ij} = \frac{1}{2} (\phi_i | \frac{1}{s} | \phi_j) + (\phi_i | \frac{1}{s} - \frac{1}{x} | \phi_j)$$

where

$$\begin{aligned} Z_{ij} &= \int \phi_i^*(x) Z(x,s) \phi_j(x) d\underline{\tau} \\ &= \int \phi_i(x) Z(x,s) \phi_j(x) d\underline{x} \end{aligned} \quad (4.17)$$

and ϕ_i is the hydrogenic eigenfunction. Now

$$\phi_{n\ell m} = R_{n\ell}(x) Y_{\ell m}(\hat{x}) \quad (4.18)$$

where the $Y_{\ell m}$ are spherical harmonics and

$$R_1 = R_{1s} = 2e^{-x}$$

$$R_2 = R_{2s} = 2^{-1/2} (1-x/2) e^{-x/2}.$$

Sack (1964) has expanded some functions of "s" in terms of Legendre polynomials,

$$Z(x,s) = \sum_{\ell=0}^{\infty} \gamma_{\ell}(x,R) P_{\ell}(\cos\theta) \quad (4.19)$$

where θ is the angle between \underline{R} and \underline{x} . For s-states the angular integrations of (4.17) are trivial and the integral reduces to

$$Z_{ij} = \int_0^{\infty} R_1 R_2 \gamma_0 x^2 dx \quad (4.20)$$

From Sack the expansion functions γ_0 for $1ns$ and s^{-2} are

$$\gamma_{0,1ns} = \ln|x-R| + \frac{(x+R)^2}{4xR} \ln \frac{x-R}{|x-R|} - \frac{1}{2} \quad (4.21)$$

$$\gamma_{0,s-2} = \frac{1}{2xR} \ln \left| \frac{x+R}{x-R} \right| \quad (4.22)$$

and the integrals (4.20) are reducible to linear combinations of the exponential integrals. Explicit forms of equations (4.16) are given in the appendix.

Unlike the usual procedure of imposing the boundary conditions (4.15) at a large but finite internuclear separation (although see Bell (1967)), the initial solutions are obtained by solving the equation (4.14) using asymptotic expansions for the matrix elements and the solutions which are valid for large negative values of the time, t . Let $\underline{\alpha}$ denote the column vector $(\alpha_i, i=1,2)$ then for large R , write the asymptotic expansions as

$$\begin{aligned} \underline{\alpha} &= \sum_{n=1}^{\infty} \frac{\underline{\alpha}^{(n)}}{R^{n-1}} & \underline{G}' &= \sum_{n=1}^{\infty} \frac{\underline{g}^{(n)}}{R^{n-1}} \\ \dot{\underline{\alpha}} &= \sum_{n=2}^{\infty} \frac{\underline{\beta}^{(n)}}{R^n} & \underline{H}' &= \sum_{n=1}^{\infty} \frac{\underline{h}^{(n)}}{R^{n-1}} \\ \ddot{\underline{\alpha}} &= \sum_{n=3}^{\infty} \frac{\underline{\gamma}^{(n)}}{R^n} \end{aligned} \quad (4.23)$$

where $\underline{g}^{(n)}, \underline{h}^{(n)}$ are square matrices. Hence from (4.14) in the asymptotic region

$$\sum_{n=3}^{\infty} \frac{\underline{\gamma}^{(n)}}{R^n} + \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} \frac{\underline{g}^{(n)} \underline{\beta}^{(m+1)}}{R^{n+m}} + \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} \frac{\underline{h}^{(n)} \underline{\alpha}^{(m)}}{R^{n+m-2}} = 0 \quad (4.24)$$

Writing

$$\dot{R} = v \left(1 - \frac{\rho^2}{R^2} \right)^{1/2} = \sum_{n=1}^{\infty} \frac{z^{(n)}}{R^{n+1}}$$

we obtain the relations

$$\underline{\beta}^{(n)} = - \sum_{m=1}^{n-1} (n-m) z^{(m)} \underline{\alpha}^{(n+1-m)} \quad (4.25)$$

$$\underline{\gamma}^{(n)} = - \sum_{m=1}^{n-1} (n-m) z^{(m)} \underline{\beta}^{(n-m)} \quad (4.26)$$

The $\underline{g}^{(n)}$ and $\underline{h}^{(n)}$ matrices can be obtained in closed form for any n , and hence from (4.24), (4.25) and (4.26), the $\underline{\alpha}^{(n)}$ vectors are found. This procedure was carried out for $n=1..8$ and the solutions and their derivatives were approximated by

$$\underline{\alpha} = \sum_{n=1}^8 \frac{\underline{\alpha}^{(n)}}{R^{n+1}} \quad \dot{\underline{\alpha}} = \sum_{n=2}^7 \frac{\underline{\beta}^{(n)}}{R^n} \quad \ddot{\underline{\alpha}} = \sum_{n=3}^7 \frac{\underline{\gamma}^{(n)}}{R^n} \quad (4.27)$$

for large R .

4. Numerical Methods

In the above analysis the amplitude and matrices were complex variables and it was convenient to separate equations (4.14) into real and imaginary parts and solve four coupled differential equations.

The starting solution for these equations at large R ($R=R_0, t=t_0$) is given by (4.27). The solution of equations

(4.22) is non-trivial especially when considering the coefficients of the higher order powers of $\frac{1}{R}$. A procedure was coded so the higher order coefficients and their derivatives could be derived on the computer using values already evaluated for $\underline{\alpha}^{(1)}, \underline{\alpha}^{(2)}$ and $\underline{\alpha}^{(3)}$. The approximate solution (4.27) was tested by checking it satisfied equation (4.14) to a pre-set precision. For example at $R=R_0=50$ ($t < 0$) we find agreement to one part in 10^{11} .

This expansion of the solution is a strict asymptotic expansion and is not valid for small R . The range of validity was tested by comparing various solutions at $t=-10$ arising from different starting positions, R_0 , and performing the time integration. On starting the time integration, it was checked that the solution ran smoothly from the asymptotic region (i.e. continuous solutions and continuous first and second derivatives). Results for three solutions with different values of R_0 are given in Table 4.1. It can be seen that the solutions $|\alpha_1|^2, |\alpha_2|^2$ are stable to one part in 10^6 at $t=-10$. For $R_0 < 12$ the asymptotic solution did not yield useful starting values.

The time integration of (4.14) was performed using a Runge-Kutta method for second order equations (Abramowitz and Stegun, 1964). In addition (4.14) were transformed into eight first order differential equations by writing

TABLE 4.1

$$\dot{\alpha}_i = \sum_{j=1}^2 G'_{ij} \alpha_j + \delta_i$$

$$\dot{\delta}_i = -\sum_{j=1}^2 \dot{G}'_{ij} \alpha_j - \sum_{j=1}^2 H'_{ij} \alpha_j$$
(4.28)

and separating into real and imaginary parts. These equations were solved with the additional boundary condition.

$$\delta_i \xrightarrow{t \rightarrow \infty} 0 \quad \text{for all } i$$
(4.29)

using either a first order Runge-Kutta or Adams-Bashforth predictor-corrector method. A sample of results for all methods are compared in Table 4.2. No attempt was made to deduce the relative merits of the integration procedures from the solutions. All that was required was that the results predicted by the various procedures for the same collision parameters, were consistent with each other. It can be seen that agreement was attained to 1%.

TABLE 4.2

predictor	0.8886	0.1589
corrector	0.8889	0.1589
Second order method		
Runge-Kutta	0.8878	0.1575

The derivative of the asymptotic solution, $\underline{\alpha}$, was found to be of order $\frac{1}{R^3}$ for large R . However in the first in the first order equation (4.28), the additional derivatives, $\dot{\delta}_i$, are of order $\frac{1}{R^2}$ for large R . This means that to obtain the same degree of stability in the solution at large R , the step length in the integration procedures for the first order equations (4.28) must be considerably smaller than that required for the second order equations (4.12). So, in the main, calculations were performed using the second order equations.

The matrix elements of \underline{G}' and \underline{H}' were coded as linear combinations of exponential integrals; all possible cancellation of terms having been performed in the analysis (see appendix). This ensured minimum round-off error in their computation. The exponential integrals were evaluated to an accuracy of sixteen significant figures. It was checked that the asymptotic forms and the exact values of the matrix elements were in agreement for large R . For $R > 40$ where the routines for the exponential integrals were inadequate, the exact matrix elements in \underline{G}' & \underline{H}' were replaced by their asymptotic forms including terms up to $1/R^7$. This proved useful in allowing the time integration to be continued to large positive times.

The matrix elements varied smoothly with time throughout the collision and their time derivatives could be obtained from a standard five-point formulae.

The computer code was written so that the equations and solutions could be transformed at $R=R_1$ say, to reintroduce the logarithmic phase factors into the solution and remove the corresponding $\frac{1}{R}$ terms from the matrix elements, thus avoiding rapid changes in the latter near $R=0$. It was found that there was no detectable change in eight significant figures in the calculated amplitudes when this transformation was made.

The step length $h=\Delta R$ ($\Delta t=\Delta R/v$) could be changed at six values of R throughout the run. In Table 4.3 solutions $|\alpha_1|^2$, $|\alpha_2|^2$ obtained from integration procedures with different mesh sizes are compared. Results predicted by the procedure using the larger mesh are in agreement to one part in 10^7 with those obtained with the finer mesh. This might be considered sufficient accuracy but for small velocities ($v<0.5$) and certain impact parameters, the excitation probability to the 2s-state is of order 10^{-7} or smaller (see fig. 4.2 below) and the crude mesh would produce an error in the probability of a comparable magnitude to the probability itself. For moderate velocities the transition probabilities are larger and an integration mesh

$$h = 0.1 \quad R > 2$$

$$h = 0.01 \quad R < 2$$

was sufficient.

TABLE 4.3

Dependence of Probabilities on the Integration Mesh Size

(The figure after the comma indicates the power of 10 by which the entry is to be multiplied).

For $t > 0$, the amplitudes $|\alpha_1|^2$, $|\alpha_2|^2$ exhibited an oscillatory behavior and this is illustrated in fig. 4.1. This behaviour hinders the task of obtaining an accurate asymptotic value of the excitation probability $|\alpha_2|^2$. Asymptotic expansions of the real and imaginary parts of the solution α_2 , of the type

$$\begin{matrix} \text{Real} \\ \text{Imag} \end{matrix} \alpha_2 = (a_0 + \frac{a_1}{R} + \frac{a_2}{R^2} \dots) \begin{matrix} \sin(f(t)) \\ \cos(g(t)) \end{matrix} \quad (4.28)$$

where $f(t) \underset{t \rightarrow \infty}{\sim} k(t)$, $g(t) \underset{t \rightarrow \infty}{\sim} k(t)$, and use of an asymptotic procedure similar to that used for large negative time, were considered as a method of obtaining the exact asymptotic amplitude a_0 . Unfortunately, although there is an overall damping of the solutions as $t \rightarrow \infty$, the amplitude of the real and imaginary parts is not in practice a monotonic decreasing function and cannot be fitted with the asymptotic solutions (4.28).

It was decided that the most expedient method to obtain an accurate asymptotic value for the amplitude was by close scrutiny of the maxima and minima of the real and imaginary parts of the solution. The modulus of the maxima and minima considered as a function of time is also a damped oscillatory function but its behaviour is such that an accurate estimate of its limit for large t can be obtained. The square of this limit was taken to be the excitation probability to the 2s-state. A few sample solutions were integrated out to $R=500$ and the above procedure gave a consistent result

FIGURE 4.1

Variation of Solutions with Time

(to 3 decimal places) for the excitation probability with that obtained from far fewer maxima and minima.

5. Results and Discussion

The calculations were carried out on the NUMAC IBM 360/67. The time taken for one computer run for one velocity and one impact parameter was, of course, mainly depended on the integration mesh size and also how far the solution was integrated out for positive time. In the main, the average time was 3 minutes but with the fine mesh used for the low velocities, the run time might be extended to anything up to 30 minutes. Since care was taken to ensure minimum cancellation in the matrix elements, computer round-off error was negligible. Results were obtained in the energy range 1 k.e.V \rightarrow 625 k.e.V from impact parameters $0 < \rho < 3 a_0$.

The transition probability as a function of impact parameter exhibited similar oscillatory behaviour at low energies as observed by Wilets and Gallaher (1966). Figure 4.2 shows the transition probability for $E=1$ k.e.V. However the final amplitudes for the $1s$ -state do not oscillate appreciably with impact parameter and furthermore in this model $|\alpha_2|^2 > 0.985$ for all impact parameters, $E < 10$ k.e.V. This is in disagreement with the experiments of Helbig and Everhart (1965) and of other theoretical calculations which include Φ_{1s}^B explicitly (Wilets and Gallaher (1966), Cheshire (1968))

Green (1965) has shown that for first order expansion methods, the sum of the probabilities is conserved throughout

FIGURE 4.2

Transition Probability at E=1 keV.

the collision. Unfortunately this does not apply to the closure approximation and for energies less than 50 k.e.V. and small impact parameters ($\rho < 1$), unitarity is violated. At $v=1$, $\rho=0.25$ the sum of the probabilities reaches its overall maximum value of 1.31. Computed values of $|\alpha_1|^2$ and $|\alpha_2|^2$ for $v=1, 2$ are given in Table 4.4.

To calculate the excitation cross-section to the 2s-state, the probabilities are replaced when necessary by

$$|\bar{\alpha}_2|^2 = |\alpha_2|^2 / (|\alpha_1|^2 + |\alpha_2|^2)$$

and are given for a range of energies and impact parameters in Table 4.5. A sample of these transition probabilities are shown in fig. 4.3 as a function of impact parameter.

Excitation cross-sections were obtained by a Simpson's integration and are given in Table 4.6 and compared with other theoretical calculations in figure 4.4.

At low energies ($E < 20$ k.e.V.) the present results lie between those of the two state calculation of Lovell and McElroy (1965) and the impulse approximation results of Coleman (1968). At intermediate energies ($25 < E < 100$ k.e.V) the results are in general agreement with the two centre hydrogenic expansion calculations of Wilets and Gallaher (1965). Gallaher and Wilets (1968) give 6-state Sturmian expansion results at two energies in this range and we also show these values.

Above 100 k.e.V., the present results lie above

those of Cheshire and Sullivan (1967) and the second Born approximation calculation of Holt and Moiseiwitch (1968). The latter are indential with the former and are not shown in fig. 4.4.

It is noticeable that in calculations which include the 1sA/1sB channel implicitly or explicitly (this includes a psuedo-state expansion calculation of Cheshire, Gallaher and Taylor (1969) which is not shown), the cross-sections peak at higher energies than for the single centre expansions. This is because the 1sA/1sB channel dominates the collision at low energies.

6. Conclusions

Direct excitation cross-sections into the 2s-state have been calculated using the closure approximation, retaining only the first two states in the expansion of the electronic wave function. An accurate asymptotic solution for large negative t allowed the time integration of the coupled equations to start at $R_0=15$. The time integration for the second order equations was performed by a Runge-Kutta method with an error term of order h^5 . The 2s-state amplitude, α_2 , was extracted for large positive t with an accuracy of three decimal figures.

The results are in reasonable accord with those of other theoretical calculations but in the absence of experimental information no conclusions can be drawn as to which method is to be preferred.

APPENDIX

The (2x2) square matrices of the second order coupled equations (4.12)

$$\ddot{\alpha}_i + \sum_{j=1}^2 G'_{ij} \dot{\alpha}_j + \sum_{j=1}^2 H'_{ij} \alpha_j = 0 \quad i=1,2$$

are given by

$$G'_{ij} = -\dot{L}_{ij} - iQ_{ij} + i \begin{vmatrix} \frac{2}{R} & \epsilon L_{12} \\ -\epsilon L_{21} & 2(\epsilon + \frac{1}{R}) \end{vmatrix}$$

$$H'_{ij} = P_{ij} + \frac{Q_{ij}}{R} - i\frac{\dot{L}_{ij}}{R} + \begin{vmatrix} -\frac{1}{R^2} & \epsilon Q_{12} - \epsilon L_{12}(\epsilon + \frac{1}{R}) \\ \epsilon \frac{L_{21}}{R} & \epsilon Q_{22} - (\epsilon + \frac{1}{R})^2 \end{vmatrix}$$

$$+ i \begin{vmatrix} -\frac{\dot{R}}{R^2} & -\epsilon \dot{L}_{12} \\ 0 & -\epsilon \dot{L}_{22} - \frac{\dot{R}}{R^2} \end{vmatrix}$$

where

$$P_{ij} = (\phi_i | \frac{1}{xs} | \phi_j)$$

$$L_{ij} = (\phi_i | \ln s^{-1} | \phi_j)$$

$$Q_{ij} = \frac{1}{2}(\phi_i | \frac{1}{s} | \phi_j) + (\phi_i | \frac{1}{s} - \frac{1}{x} | \phi_j).$$

The exponential integrals are defined as

$$E_1(x) = \int_x^\infty \frac{e^{-t}}{t} dt$$

$$E_i(x) = - \oint_{-x}^\infty \frac{e^{-t}}{t} dt.$$

Let

$$\bar{E}_1 = \bar{E}_1(\lambda R) = e^{\lambda R} E_1$$

$$\bar{E}_i = \bar{E}_k(\lambda R) = e^{-\lambda R} E_i$$

then

$$P_{11} = \frac{1}{R} \left(1 - e^{-\lambda R} \right)$$

$$-L_{11} = \ln R + \frac{1}{4} \left(\bar{E}_1 \left(\frac{3}{\lambda R} - 1 \right) + \bar{E}_i \left(\frac{3}{\lambda R} + 1 \right) \right)$$

$$\lambda = 2$$

$$Q_{11} = \frac{\bar{E}_1}{2} \left(\frac{1}{\lambda R} - 1 \right) + \frac{\bar{E}_i}{2} \left(\frac{1}{\lambda R} + 1 \right) + \frac{1}{R} \left(1 - e^{-\lambda R} \right) - e^{-\lambda R} - 1$$

$\lambda = 2$

$$P_{12} = P_{21} = \frac{1}{2^{1/2} \lambda^2} \left(\frac{1}{\lambda R} (1 - e^{\lambda R}) + e^{-\lambda R} \right)$$

$$-L_{12} = -L_{21} = \frac{1}{2^{1/2} \lambda^3} \left(\frac{1}{\lambda} - \bar{E}_1 \left(\frac{\lambda R}{3} - 1 + \frac{1}{\lambda R} \right) - \bar{E}_i \left(\frac{\lambda R}{3} + 1 + \frac{1}{\lambda R} \right) \right)$$

$$Q_{12} = Q_{21} = \frac{2^{1/2}}{8 \lambda^3 R} \left(\bar{E}_1 (1 - \lambda R - \lambda^2 R^2) + \bar{E}_i (1 + \lambda R - \lambda^2 R^2) + 2 \lambda R \right) \\ + \frac{1}{2^{1/2} \lambda^3} e^{-\lambda R} (\lambda R + 1) - \frac{1}{2^{1/2} \lambda^3}$$

$$\lambda = 3/2$$

$$P_{22} = \frac{1}{8} \left(\frac{2}{R} - \frac{2}{R} e^{-\lambda R} - R e^{-\lambda R} \right)$$

$$-L_{22} = \ln R + \frac{1}{8} \left(-6 + \bar{E}_1 \left(\frac{12}{R} - 8 + \frac{5}{2} R - \frac{1}{2} R^2 \right) + \bar{E}_i \left(\frac{12}{R} + 8 + \frac{5}{2} R + \frac{1}{2} R^2 \right) \right)$$

$$Q_{22} = \frac{1}{32 R} \left(\bar{E}_1 (2 - 2 R - R^2 - R^3) + \bar{E}_i (2 + 2 R - R^2 + R^3) \right) \\ + \frac{1}{8} \left(\frac{8}{R} - e^{-\lambda R} \left(\frac{8}{R} + 6 + 2 R + R^2 \right) \right) - \frac{1}{4}$$

$$\lambda = 1$$

A classical model for electron and proton impact ionization

G. W. CATLOW and M. R. C. McDOWELL

Mathematics Department, University of Durham

MS. received 12th June 1967

Abstract. Ionization cross sections of He, Li, O and N by electrons and protons are calculated in a classical model, and compared, where possible, with quantal calculations and experiment.

1. Introduction

Recently, classical calculations of electron and proton impact ionization of atomic hydrogen by Kingston (1966), McDowell (1966), Percival and Valentine (1966) and Vriens (1967) have shown that such models can predict accurate values of the cross section for such processes at low and moderate energies (up to proton energies of say 200 kev).

It is of interest to extend the calculations to other atomic species. The model adopted is essentially that of Gryzinski (1965), as modified by Stabler (1964) and Vriens (1967). That is to say, the atomic electrons are regarded as distinguishable, and interact separately with the incident particle, the binding potentials being neglected during the collision. It is thus a binary encounter classical impulse approximation.

In this paper the atomic electrons are taken to have a momentum distribution given by the Fourier transform of the Hartree-Fock density distribution.

The analysis is outlined in § 2, and the calculations described and compared with other estimates and the available experimental data in § 3.

2. Theory

Following McDowell (1966) if V_1 , V_2 are the velocities in atomic units of the bound electron and the incident particle, and $u = V_0^2$ is the ionization potential in rydbergs, then introducing dimensionless variables s , t

$$s^2 = V_2^2/V_0^2, \quad t^2 = V_1^2/V_0^2 \quad (1)$$

the ionization cross section for an incident particle of energy $m_2 s^2 u$ rydbergs (where m_2 is the mass of the incident particle in electron units) is

$$Q(s) = N \int_0^\infty f(t) Q(s, t) u^{1/2} dt \quad (\text{in units of } \pi a_0^2) \quad (2)$$

(including only the contribution of the N electrons in the outermost shell). Here $f(t)$ is the momentum distribution of a single electron in this shell, and $Q(s, t)$ is the cross section for ionization of a bound electron of energy $t^2 u$.

For electron impact (Stabler 1964, McDowell 1966)

$$\begin{aligned} u^2 Q(s, t) &= \frac{4}{3s^2} \frac{2(s^2 - 1)^{3/2}}{t} & 1 \leq s^2 \leq t^2 + 1 \\ &= \frac{4}{3s^2} \left\{ (2t^2 + 3) - \frac{3}{s^2 - t^2} \right\} & s^2 \geq t^2 + 1 \end{aligned} \quad (3)$$

and for proton impact it follows readily from Vriens (1967) that

$$\begin{aligned} u^2 Q(s, t) &= \frac{4}{s^2} \left\{ 1 + \frac{2t^2}{3} - \frac{1}{4(s^2 - t^2)} \right\} & 1 \leq 4s(s - t) \\ &= \frac{2}{s^2 t} \left[\frac{1}{4(s + t)} + t + \frac{2}{3} \{ 2s^3 + t^3 - (1 + t^2)^{3/2} \} \right] & 4s(s - t) \leq 1 \leq 4s(s + t) \\ &= 0 & 1 \geq 4s(s + t) \end{aligned} \quad (4)$$

for all atomic systems. The momentum distribution $f(t)$ is given by

$$f(t) = 4\pi t^2 u \rho_{nl}(tu^{1/2}) \quad (5)$$

where $\rho_{nl}(\mathbf{x})$ is defined by

$$\rho_{nl}(\mathbf{x}) = \rho_{nl}(\mathbf{x}) = \frac{1}{2l+1} \sum_{m=-l}^{+l} |\Psi_{nlm}(\mathbf{x})|^2. \quad (6)$$

Here

$$\Psi_{nlm}(\mathbf{x}) = \frac{1}{(2\pi)^{3/2}} \int \Phi_{nlm}(\mathbf{r}) e^{i\mathbf{x}\cdot\mathbf{r}} d\mathbf{r} \quad (7)$$

in which $\Phi_{nlm}(\mathbf{r})$ is a one-electron orbital.

The normalization is

$$\int \rho_{nl}(\mathbf{x}) d\mathbf{x} = 1. \quad (8)$$

The $\Phi_{nlm}(\mathbf{r})$ were taken to be of the form

$$\Phi_{nlm}(\mathbf{r}) = N_{nl} R_{nl}(r) Y_{lm}(\Omega)$$

where N_{nl} is a normalization constant and $R_{nl}(r)$ are Hartree-Fock radial functions (Roothaan, Sachs and Weiss 1960, Roothaan, Clementi and Yoshimine 1962, Roothaan and Kelly 1963).

3. Results and discussion

Ionization cross sections have been calculated for H, He, Li, O and N. The results for hydrogen are in agreement with earlier work.

For electron impact two alternative sets of results are presented: the initial calculations were used in (2) above to give a value Q_1 and were subsequently modified (Q_2) by taking

$$f(t) = 0, \quad t > s \quad (9)$$

(see Kingston 1966), that is collisions in which the incident electron is the slower of the two are neglected. This agrees with the procedure used in a quantal calculation when exchange is neglected (Peterkop 1961). The experimental results for electron impact ionization are taken from the critical review by Kieffer and Dunn (1966) and from McFarland (1967).

In cases where the ground configuration of the residual ion gives rise to more than one electronic state (e.g. O^+ , N^+) an average ionization potential (Slater 1960) is used. The results for electron impact are presented in figures 1 (a), (b), (c) and (d). In general Q_1 is too large, though the situation for atomic nitrogen is not clear, as Peterson's (1964) experimental values may be preferable, although much larger than the generally accepted values (Smith 1962). If Boksenberg's (1961) results for atomic oxygen are too high, our calculations would lend support to the view that the Smith values are to be preferred for nitrogen.

Our results for Q_2 at energies up to 250 eV are always within a factor or two of experiment, and are in general much closer to experiment than this, particularly for Li and He. The agreement in Li may not be relevant, in view of the uncertainty attaching to the experimental values until the discrepancy at high energies between these and the Born calculations is resolved.

Only Q_1 is relevant for proton impact. The results are shown in figures 2 (a), (b), (c) and (d). The only comparison with experiment that is possible is excellent below 200 keV. At high velocities ($s^2 > 20$) the proton and electron cross sections agree closely. Both fall off as s^{-2} as $s \rightarrow \infty$.

When $u^2 Q(s)/N$ is considered as a function of s , it is found that in this model curves for H and Li, and for N and O are quite similar (in each pair), but there does not appear to be any universal curve which will fit all the calculations to better than $\pm 30\%$.

As the number of electrons in the outer shell increases the error in the prediction of the model appears to increase proportionately.

Various methods have been proposed for including continuum contributions in eigenfunction expansions for the proton-hydrogen atom problem. Calculations for the process

discussed in this paper have been reported in the impulse approximation (Coleman 1967), a Sturmian expansion (Callaher and Wilets 1967) and in an angular momentum expansion (Cheshire and Sullivan 1967), all of which include some continuum contributions.

We report briefly on results obtained using a closure approximation due to Cheshire (1965)*. Adopting the notation of that paper, and working in an impact parameter formulation, the time dependent Schrodinger equation for the electronic wave function becomes

$$(T_A + V_B)\Psi = (T_B + V_A)\Psi = 0 \quad (1)$$

where

$$T_A = \frac{1}{2} \nabla_r^2 + \frac{1}{s} + i \frac{\partial}{\partial t}, \quad V_B = \frac{1}{x} \quad (2)$$

$$T_B = \frac{1}{2} \nabla_r^2 + \frac{1}{x} + i \frac{\partial}{\partial t}, \quad V_A = \frac{1}{s}$$

*The numerical results given in that paper should be disregarded.

*National Academy of Sciences - National Research Council Resident Research Fellow.

†On leave of absence, 1967-8, from University of Durham.

If $\phi_n(\underline{s})$ is a hydrogen atom eigenfunction, the electron being on proton A, then

$$|A \rangle_n = \phi_n(\underline{s}) \exp \left\{ -i \left(\frac{1}{2} \underline{v} \cdot \underline{r} + \frac{1}{8} v^2 t + \epsilon_n t \right) \right\} \quad (3)$$

satisfies

$$T_A |A \rangle_n = 0. \quad (4)$$

Defining the parallel set of states $|B \rangle_m$ on B and expanding Ψ alternatively as

$$\Psi = \sum_k \alpha_k |A \rangle_k = \sum_j \beta_j |B \rangle_j \quad (5)$$

yields first order coupled equations

$$\dot{\alpha}_k = i \langle A | V_B | B \rangle \beta_j \quad (a) \quad (6)$$

$$\dot{\beta}_k = i \langle B | V_A | A \rangle \alpha_j. \quad (b)$$

Now differentiate (6a) with respect to time and eliminate the $\dot{\beta}_k$ using (6b) and closure

$$\sum_k |B \rangle_k \langle B_k| = 1 \quad (7)$$

to obtain

$$\ddot{\alpha}_k - i \langle A | V_B T_B V_B^{-1} | A \rangle \dot{\alpha}_k + \langle A | V_B V_A | A \rangle \alpha_k = 0 \quad (8)$$

subject to the boundary conditions

$$\alpha_{k1} \sim \delta_{k1} e^{-i \int_{-\infty}^t \frac{1}{R} dt'} \quad (9)$$

We have solved (8) in a two-state approximation retaining the 1s and 2s states of A explicitly. A four state (1sA, 2sA, 2p₀A, 2p-A) calculation is in hand.

Noting that

$$\langle A | V_B T_B V_B^{-1} | A \rangle = \langle A | V_B (T_A + V_B - V_A) V_B^{-1} | A \rangle$$

and that

$$\langle A | V_B T_A V_B^{-1} | A \rangle = -i \frac{d}{dt} \langle A | \ln V_B | A \rangle + \langle A | \left(\frac{1}{2} V_B^2 \right) | A \rangle$$

(8) becomes

$$\ddot{\alpha}_k + \gamma \dot{\alpha}_k + H \alpha_k = 0 \quad (8')$$

where

$$\gamma = -\frac{d}{dt} \langle A | \ln V_B | A \rangle + \frac{1}{2} \langle A | V_B^2 | A \rangle + \langle A | V_B - V_A | A \rangle$$

$$H = \langle A | V_B V_A | A \rangle.$$

It is convenient to rewrite (8') in Hamiltonian form as

$$\dot{\underline{\alpha}} = \underline{V} \underline{\alpha} + \underline{\delta} \quad (10)$$

$$\dot{\underline{\alpha}} = (\underline{V} - E) \underline{\alpha}$$

with the boundary conditions $\underline{\alpha}_n \sim 0$ (all n). Introducing the real and imaginary parts of $\underline{\alpha}$, $\underline{\delta}$ and retaining n states (9) becomes

$$\dot{\underline{\alpha}} = G \underline{\alpha} \quad (11)$$

where $\underline{\alpha}$ is a $4 \times n$ dimensional column vector.

In solving (11) we first obtain asymptotic series ($t \rightarrow -\infty$) for the α_k ($k = 1, 2$) after removing the logarithmic phase factors. Reintroducing these phase factors (so that all the elements of G are regular near $R = 0$) (11) is solved either by Runge-Kutta-Gill or Adams-Bashforth techniques. The solutions at large positive time behave as

$$\begin{matrix} \text{Re} \\ \text{Im} \end{matrix} (a_{2s}) = (A_{2s} + \frac{a_0}{t} + \frac{a_1}{t^2} + \dots) \begin{matrix} \cos \\ \sin \end{matrix} (\epsilon t + b_0 + \frac{b_1}{t} + \dots)$$

and $A_{2s}^2(+\infty)$ may be extracted without difficulty.

In general the computed values of A_{1s}^2 , A_{2s}^2 do not satisfy unitarity, their sum being as large as 1.12 for small velocities and small impact parameters, and are replaced by

$$\bar{A}_{2s}^2 = A_{2s}^2 / (A_{1s}^2 + A_{2s}^2).$$

This is expected, as the expansion includes the $1sA$ and $2sA$ states both explicitly and in the closure.

Calculations were carried out in the energy range $6.25 \leq E_1 \leq 100$ keV, for impact parameters in the range $0 < \rho \leq 3.0 a_0$. The asymptotic

solutions were interval and integration method dependent to 1% accuracy, the forward integrations being stopped at $t = +70$ in general. Transition probabilities for four energies as a function of impact parameter are shown in Fig. 1. The values of A_{2s}^2 obtained nowhere exceed 0.5. For $E_1 = 6.25$ keV a double peak is obtained as in Lovell and McElroy's work.

In Fig. 2 we compare our values of the calculated cross section

$$Q_{1s \rightarrow 2s} = 2 \int_0^\infty \rho A_{2s}^2(\rho, V) (\pi a_0^2) d\rho$$

with those obtained in other models. At low energies our results lie between those of the 1s-2s (without closure, McElroy and Lovell 1965) and impulse (continuum only, Coleman 1967) calculations. At higher energies (> 40 keV) our results are larger than those obtained in other models (with the possible exception of the 12-state Sturmian expansion, Wilets and Gallaher 1967). In comparing with Cheshire and Sullivan's "all s + all p" non-adiabatic calculation it should be noted that the present model, but not theirs, implicitly allows for the 1sA/1sB rearrangement which should reduce the value of A_{2s}^2 at low energies (< 40 keV) where that channel dominates. At higher energies the present model, which makes some allowance for d and higher states and implicitly contains part of all of them lies, not unreasonably, above the "all s" and "all s + all p" sequence.

We have shown the 12-state Sturmian result from 20 to 45 keV only, as Gallaher and Wilets compute results at 25 and 40 keV only. Their approach is rather similar to ours, but includes rearrangements explicitly. The general trend compares well with our results. Both

our results and those of Gallaher and Wilets are in strong disagreement with the impulse approximation prediction. It would appear that this is due to including bound intermediate in addition to continuum intermediate states. Perhaps experiment may resolve the ambiguities.
